Solid-state NMR is a powerful tool for the study of surfaces and interfaces in polymer composites and nanocomposites. The NMR spectra and relaxation parameters are sensitive to the structure and dynamics on a very local length scale, allowing us to probe the polymer properties at the interface. The introduction of multidimensional NMR provides new opportunities to characterize in detail the structure and dynamics of polymers at surfaces and interfaces.

The Structure of Polymer Networks

Andrew K. Whittaker
Centre for Magnetic Resonance, The University of Queensland, Queensland 4072, Australia

Introduction

Network polymers comprise one of the most important classes of polymeric materials, from both a theoretical and a commercial perspective. The linking together of macromolecular chains usually through permanent covalent bonds confers unique properties to network polymers. These may be increased modulus and elasticity, lower rates of creep, solvent resistance, high temperature stability, to name just a few. The applications of network polymers are thus myriad. Thermosetting resins comprise the majority of polymers used in structural applications. Crosslinked polyolefins are ubiquitous as automotive tyres, as a component of asphalt, as o-rings, sheeting, in clothing and footware and so on. In more recent times, chemically crosslinked networks are becoming important in the field of biomaterials, as supports for tissue growth and for drug delivery. Many other applications can be listed.

From the point of view of the NMR spectroscopist, the structural features that provide networks their unique physical properties give rise to a number of experimental challenges. Network polymers are by definition wholly or largely insoluble, and therefore conventional solution-state NMR techniques cannot be routinely applied to their analysis. Resort must be made to solid-state NMR techniques, or to other methods for narrowing the dipolar-broadened line shapes. To compensate for this difficulty in extracting chemical information, there are a number of other NMR techniques for determining physical structure, for example, crosslink density, molecular weight between entanglements, and pore or mesh size.

Thus, the aim of this review is to summarize the development of NMR methodologies for the study of network polymers, in particular the determination of chemical structure and network properties using high-resolution NMR and NMR relaxometry. We are not concerned in this review with other aspects of network behavior, for example, the motion of penetrants in polymer networks, or NMR imaging of networks, as these aspects are covered in depth elsewhere in this monograph. All of these issues have been addressed in detail on a number of reviews specifically within the field of NMR characterization of networks [1–6], as well as a number of reviews on general analytical methods, including NMR, for characterizing polymer networks [7–9].

The Chemical Structure of Polymer Networks

The Effect of Network Structure on NMR Linewidths

The inherent insolubility of polymer networks and the connectivity of polymer chains result in relatively large unaveraged dipole–dipole couplings compared with small molecules freely tumbling in solution. As a result under normal experimental conditions, the NMR lines become broadened. This is a fact that has been exploited for a number of crosslinked network polymers. For example, Tinker and coworkers [10,11] developed qualitative relationships between the crosslink density and the widths of the peaks in the ^{1}H NMR spectra of natural rubber (NR) and other elastomers. Although it is not possible using their approach to construct a comprehensive theory relating the mechanism of line broadening with the extent of network formation, the value of this work lies in the ability to provide a rapid measurement of crosslink densities in blended and filled systems [12].

Another manifestation of the increase in linewidth on an increase in network density is a decrease in the overall signal amplitude achievable using high-resolution NMR techniques. Ford and coworkers [13–16] have produced a series of papers on the NMR characterization of poly(styrene) (PSTY) resins. In their initial report [14], poly(styrene) resins were prepared using a range of concentrations of divinyl benzene crosslinking agent. The samples were swollen to equilibrium with deuterated chloroform and measurements were made of T_1 relaxation times, ^{13}C linewidths, and NOE factors using a conventional solution-state NMR spectrometer. The magnitude of T_1 was relatively unaffected by crosslinking, indicating little change in the spectral density of motions in the MHz frequency range. This insensitivity of the high frequency motions to crosslinking has been noted on a number of occasions. However, for these swollen crosslinked PSTY materials, the linewidth increased with increasing crosslink density. Most significantly, the intensity of the

Graham A. Webb (ed.), Modern Magnetic Resonance, 583–589.
© 2008 *Springer.*

peaks decreased markedly, and the peaks associated with the aliphatic backbone carbons being more strongly affected than those due to the aromatic side chains. The loss of intensity was ascribed to inefficient decoupling of the dipole–dipole interactions both by the scalar ^{1}H decoupler and by the effects of restricted molecular motion.

It was concluded that in these experiments only parts of the polymer structure are being detected and that chain segments near to crosslink points were not visible. In a later study, Mohanraj and Ford [13] have attempted to account for the decrease in intensity in the ^{13}C spectra of crosslinked poly(chloromethylstyrenes) in a more quantitative manner. The decrease in signal intensity was analyzed and it was concluded that carbon nuclei in crosslinks as well as uncrosslinked units within one or two units of crosslink points are not observed. Similar conclusions were reached by O'Donnell and Whittaker [17] who examined ethylene–propylene rubbers crosslinked using a range of gamma radiation doses. At low crosslink densities, a small peak due to methine carbons in so-called H-type crosslinks was observed, with the width of this peak increasing with increasing levels of crosslinking, until the line could not be resolved from the baseline. It is thus evident that at even higher levels of crosslinking, other NMR techniques need to be utilized.

The method of magic angle spinning (MAS) will be discussed in greater depth elsewhere in this text. Briefly, in the absence of isotropic motion, the NMR line shape is dominated by strong dipole–dipole couplings to neighbor protons, and for ^{13}C the relatively large anisotropy of the chemical shift tensor. The technique of MAS deals effectively with the latter of these line broadening mechanisms, since rapid rotation of the sample around the magic angle leaves observable only the trace of the tensor, i.e. the isotropic chemical shift. Rotation at intermediate spinning speeds results in a series of rotational echoes in the FID, which on Fourier transformation results in evenly spaced spinning side bands. MAS also partially averages both the homonuclear and the heteronuclear dipole–dipole couplings, and hence high-power proton decoupling during ^{13}C acquisition is required to fully remove this contribution in ^{13}C NMR spectroscopy.

An example of the application of these techniques to the analysis of swollen crosslinked polymers has been was provided by Stöver and Fréchet [18,19] who have shown that MAS and dipolar decoupling reduce the ^{13}C linewidth in spectra of an ephedrine-functionalized divinylbenzene-styrene copolymer to values similar to those observed for uncrosslinked polymers. The relative peak intensities in the spectra are close to those predicted from the known structure of the polymer. In a related study [19], the authors suggest the use of crosspolarization (CP) to observe selectively crosslink points in the polymer gels.

A large number of polymer networks, most notably the thermosetting resins, are cured at elevated temperatures and hence under ambient conditions are well below their glass transition (T_g) or softening temperature. These rigid solids often have broad, poorly resolved ^{13}C NMR spectra, even with the use of MAS and high-power decoupling. A suggested approach to reduce the linewidth and to achieve high resolution is to record the spectra above the T_g temperature. Until recently most commercial MAS probes were limited to a maximum temperature of around 423 K, often well below the T_g of crosslinked resins. Recent advances in probe design have, however, allowed much higher temperatures to be reached in the MAS rotor. Sterna and Smith [20] were the first to demonstrate the advantages of improved resolution in ^{13}C spectra of thermosetting resins recorded above T_g. The spectra of diglycidyl ether of bisphenol A (DGEBA) reacted with and bisphenol acetone recorded at 473 K display liquid-like resolution, enabling, for example, the authors to identify a small peak due to the methine carbon in etheric crosslink structures. More recently, Harris *et al.* [21] studied the structure of the matrix formed by reaction of DGEBA with diamino diphenyl sulfone. The increase in resolution due to averaging of conformations otherwise frozen below T_g is dramatic.

Crosslinked Polyolefins

The vulcanization of NR with sulfur was first performed in 1841, and since then has become the basis of the enormous motor vehicle tyre industry. The mechanism of vulcanization/crosslinking is complex and despite much study, many aspects remain unresolved. For example, addition of the sulfur can occur at the double bonds, as in unaccelerated cure or at one of the allylic positions, as in accelerated vulcanization. The distribution of crosslinking and other reactions depends not only on the extent of compounding of the reactants and the rubber resin but also the mechanism of reaction, as is discussed below.

The analysis of the vulcanization or crosslinking of rubber materials has been the subject of an extensive series of publications by Koenig and coworkers [22–24], and the findings of which are summarized in several reviews [3,25]. The authors have attempted to determine the mechanisms of the very wide range of reactions that occur in vulcanization and other crosslinking reactions. In their early work, Zaper and Koenig [26,27] studied the reaction of sulfur with NR and reported profound changes in the ^{13}C NMR spectra on curing. They reported an increase in linewidth on curing due to a decrease in segmental motion on crosslinking, and the appearance of new peaks on both the high field and low field sides of the peaks in the aliphatic region. At higher levels of cure, the resolution in the ^{13}C spectra deteriorated and much of the chemical information was lost. Despite this, the structure of the methine groups in polysulfidic crosslinks was determined and the intensities of the peaks associated with these structures were shown to be inversely proportional to the swelling ratio. Other new peaks in the spectra were assigned to carbons in crosslink structures in which addition of sulfur had occurred at all four possible sites adjacent to the double bonds. In addition, the presence of cyclic structures was confirmed.

Fuelber and coworkers [28,29] have demonstrated the utility of an experiment that correlates the decay of transverse magnetization of the ^{1}H spins with the ^{13}C chemical shift, by crosspolarizing residual ^{1}H magnetization to the ^{13}C nuclei. The decay of ^{1}H magnetization of sulfur-cured poly(styrene-co-butadiene) rubber could be described by the sum of Gaussian and Lorentzian decays, corresponding to relatively rigid and mobile parts of the polymer, respectively. The second moment of the Gaussian line shape and the inverse of the T_2 of the Lorentzian line shape were seen to increase with increasing crosslinking density, consistent with restriction of motion of the main and side chains on crosslinking. These aspects will be discussed in more detail below.

An important method of crosslinking polyolefins is by exposing the material to high-energy radiation, initiating the formation of free radicals that undergo a range of reactions including crosslinking. As the concentration of crosslinks approaches one link on average per chain, the polymer reaches the gel state and is largely insoluble. The concentration of crosslinks at the gel point for polymers with initially high-molecular weight is very small of the order of one carbon per 10^4–10^5 carbons in the main chain. For this reason, model compounds which remain soluble when irradiated to high doses were initially examined. Bennett *et al.* [30] reported the formation of H-type crosslinks in irradiated liquid *n*-hexadecane and *n*-eicosane. Bovey *et al.* [31] observed H-links and long chain branching (Y-links) in n-$C_{44}H_{99}$ irradiated in the melt, whereas irradiation in the crystalline state gave only linear dimers, apparently through endlinking of the chains at surface of the crystals.

Randall and coworkers [32,33] were the first to report the structures of crosslinks in irradiated high molecular weight polymers using solution-state ^{13}C NMR. Y-links were detected in linear poly(ethylene) irradiated to below the gel dose at 298 K. On the other hand, H-links were observed when the irradiation temperature was increased to 550 K, i.e. in the molten state. The authors suggested that the major linking reaction at low doses involved addition of main chain alkyl radicals to double bonds initially present in linear poly(ethylene) as chain ends. A more complete study of crosslinking in irradiated low molecular weight fractions of linear poly(ethylene) was subsequently made by Horii and coworkers [34,35]. These authors were able to observe changes in the relative contribution of the various mechanisms of crosslinking on irradiation at different temperatures and related this to the relative stability of alkyl free radicals. These papers in particular present information on network formation vastly superior to that obtainable with other spectroscopic techniques.

An issue of some importance is the distribution of crosslinks in cured polyolefins, as this determines the efficiency of the added crosslinking agent (or high-energy photons) and many subsequent network properties. This issue was initially addressed using NMR by O'Donnell and Whittaker [36] who used ^{13}C CPMAS NMR to determine the crosslink density of ethylene–propylene rubbers irradiated to very high radiation doses. The yields for crosslinking and scission estimated from the NMR peak intensities are in excellent agreement with values obtained from measurements of the soluble fractions, a more traditional though time-consuming technique. The estimation of yields of crosslinking from measurement of soluble fractions necessitates several assumptions, namely a most probable initial molecular weight distribution and random crosslinking reactions. The excellent correspondence between the two sets of results underlines the validity of these assumptions in this case.

In contrast to this, the formation of networks by gamma irradiation of *cis*-1,4-poly(butadiene) (*cis*-PBD) and other polydienes [37–43] proceeds through a chain reaction involving addition of radical species to double bonds. Barron *et al.* [37] and O'Donnell and Whittaker [39] have measured the changes in the ^{13}C CPMAS spectra of *cis*-PBD samples irradiated to various doses up to 10 MGy. With increasing dose, there is a progressive decrease in the intensity of the peak due to double bonds, and the appearance of a broad peak assigned to methine carbons in crosslinked structures. Spectra were recorded using a range of CP contact times up to 25 ms, and the results were interpreted to yield quantitative yields of crosslinking and for loss of double bonds. Very high yields of reaction indicative of chain reactions were determined, in particular values much higher than the yields determined using solution methods. These results indicate a highly heterogeneous distribution of crosslink reactions, as a result of successive radical addition to double bonds. Other evidence of the heterogeneity of crosslink reactions during radiolysis is the report by Patterson and Koenig [44] of the radiation crosslinking of NR, *cis*-poly(isoprene), studied by solid-state ^{13}C NMR. A highly heterogeneous structure was evidenced by differences in the spectra obtained by direct polarization of the ^{13}C nuclei, and those obtained using CP.

The characterization of chemical changes during network formation of polydienes is aided by the very high yields of reaction resulting in marked changes to the NMR spectra. A more challenging problem is the characterization of the network structure in crosslinked poly(ethylene), i.e. poly(ethylene) crosslinked beyond the gel point. Cholli and coworkers [45] were the first to convincingly demonstrate the direct observation of crosslinks in poly(ethylene) by solid-state NMR. ^{13}C CP-MAS NMR spectra of high-density poly(ethylene) irradiated to high doses showed two small new peaks assigned to methine carbons in Y- and H-links, respectively. The formation of Y-links or branches was confirmed by the appearance of new peaks at lower chemical shift due to branch structures. O'Donnell and Whittaker [46] later reported the changes in crystalline content and lamellar dimensions after crosslinking using DSC and ^{1}H spin diffusion measurements. A peak assigned to methine carbons in H-crosslinks was also reported, and the yield of crosslinks obtained from analysis of the NMR spectra was very close to the yield obtained from analysis of the soluble fraction. It was therefore concluded that crosslinking occurs randomly throughout the amorphous phase of poly(ethylene).

Thermosetting Resins

In this review, the application of high-resolution NMR to the study of epoxy resins will be briefly discussed. The characterization of many other thermosetting network systems by NMR has been reviewed in detail elsewhere [2,8,47] and in general provides for the spectroscopist the same challenges of poor resolution in structurally diverse materials. Epoxy resins are an important class of materials used extensively in coatings and structural applications. Many end-use properties, not least long-term mechanical and chemical stability, are determined by the precise details of the curing reactions. Thus, questions of interest to the chemist which can be resolved by NMR spectroscopy include the mechanism of cure and extent of reaction of the secondary amine groups, and in particular the effect of filler on curing chemistry, a problem not easily amenable to other spectroscopic analyses. At low cure conversions, it is possible to follow the chemical changes using conventional solution-state NMR [48–52]. However, when the viscosity of the resin increases as cure proceeds and the ^{13}C lines broaden considerably, resort must be made to solid-state NMR techniques.

The dramatic changes in composition and chain dynamics that accompany curing of a thermosetting resin have been studied using ^{13}C MAS NMR by Haw and Johnson [53]. Their work was concerned with the curing of DGEBA with tetraethylene tetraamine at 323 K from the liquid state through the gel state and into the solid state. At low levels of cure, the high-resolution NMR spectrum gave information comparable to that obtained by conventional high-resolution spectroscopy; however, as the reaction continued and the extent of cure increased, the overall signal intensity decreased and the lines became progressively broader, for reasons discussed above. At even longer curing times, ^{13}C CPMAS NMR was used to measure changes in the chemical structure.

The first solid-state NMR study of an epoxy resin was presented by Garroway *et al*. in 1978 [54]. In this work, they were concerned with investigating the quantitative aspects of the NMR technique as applied to resins of DGEBA cured with four amine/anhydride mixtures. While all the features of the solution-state spectra at low conversion are replicated in the solid-state spectra, the much larger line width in the solid-state limits the amount of chemical information available from the ^{13}C NMR spectra. The increase in line width is ascribed mainly to increased dispersion of isotropic chemical shifts due to the presence of a large number of frozen conformations in the glassy cured matrix. As discussed above, raising the temperature [20,21] to above the T_g results in line narrowing and reattainment of high-resolution conditions.

The Physical Structure of Polymer Networks

Changes in T_2 Relaxation Times

As discussed above, one manifestation of network formation is an attenuation of segmental motion of the polymer backbone, and as a consequence one observes an increase in the NMR line widths. To state this in other terms, the formation of a network has a profound effect on transverse relaxation times of a polymer above its T_g temperature or of a swollen polymer network. The decrease in segmental mobility is most important at sites adjacent to crosslink points, so that the amplitude of motion of a particular chain segment increases the further that point is from the crosslink, or indeed the closer the segment is to a chain end. In practice, the decay of transverse relaxation in a crosslinked polymer can be decomposed into usually two or more decay processes. The more rapid decay process can be broadly assigned to segments close to crosslinks, while the slower decay to segments well removed from the crosslinks, or close to chain ends. Therefore, the decay of magnetization can be described by:

$$M(t) = \sum M_i(0)\, e^{-(t/T_2^i)} \,. \tag{1}$$

Here, M_i and T_2^i are the amplitude and time constant of the ith decay process, respectively, and i can take the values 1, 2, 3, ... It is important to note that M_1, i.e. the amplitude of the fastest decay, does not give a direct measure of the number of crosslinks, but rather the number of segments adjacent to the crosslinks, and hence is proportional to the crosslink density.

Arthur Charlesby and coworkers [55–61] were amongst the first to use measurements of T_2 to follow the formation of crosslinked polymer networks. In early work [57,58], they studied the changes in T_2 relaxation times of poly(dimethyl siloxane) when crosslinked by exposure to gamma radiation. The molecular weights of all polymers investigated were above the critical molecular weight for entanglement prior to irradiation, and therefore, the T_2 relaxation decays were decomposed into two separate processes, with the short relaxation decay containing a contribution from chain entanglements. Charlesby accounted for this by introducing the concept of a "virtual radiation dose" received by the unirradiated materials appropriate to the degree of chain entanglement experienced by these polymers. The authors were able to determine from the decrease in amplitude of the slow relaxation decay (due to chain segments removed from crosslink points) the yields of radiochemical reactions and found results in good agreement with those determined by solution methods. Charlesby and coworkers extended this approach to a number of other network systems with some success [62–64], and this approach has formed the basis of many subsequent studies of network formation.

Estimation of Residual Dipolar Coupling

While it is generally accepted that the slowest transverse relaxation processes in polymer networks can be represented by exponential decay functions, it is equally well accepted that the decay of magnetization at short times conforms more closely to a Gaussian decay function. In their work, Folland and Charlesby [55] recognized this but indeed were more concerned with following the changes in the relative proportions of the fast and slow decay functions, and thereby estimating the crosslink density.

Simon and coworkers [65–68] have developed a model of T_2 relaxation in which the faster decay process arises from an "intercrosslink" component of the network, in which motion is rapid and anisotropic and does not average to zero the dipolar interactions. The rapid motion, described by a correlation time τ_{f}, occurs simultaneously with a slower isotropic motion, described by the correlation time τ_{s}, of the complete intercrosslink segment. The longer relaxation decay arises from dangling chain ends and is exponential in nature. The total decay of transverse magnetization is then given by:

$$\frac{M_{x,y}(t)}{M_{x,y}(0)} = A\exp\left\{\frac{-t}{T_2} - qM_2\tau_s^2 \times\left[\exp\left(\frac{-t}{\tau_s}\right)+\frac{t}{\tau_s}-1\right]\right\} + B\exp\left(\frac{-t}{T_2}\right). \tag{2}$$

Here, M_2 is the second moment of the rigid-lattice line shape, q the fraction of the rigid-lattice second moment unaveraged by the anisotropic motion, and $1/T_2 = M_2\tau_{\mathrm{f}}$. In addition, a second slower process represented by the last term in Equation (2) and contributing close to 5% of the total signal amplitude was ascribed to a low molecular weight sol fraction. It was argued that the parameter q, the degree of averaging of the rigid-lattice second moment, could be related to the molecular weight between crosslinks M_{c} as:

$$M_{\mathrm{c}} = \frac{3cMru}{5n\sqrt{q'}}. \tag{3}$$

Here, q' is the above parameter q for a crosslinked network minus the contribution from physical entanglements, q_{o}, measured for an uncrosslinked material.

This method was more recently applied by Menge *et al.* [69] to the study of swollen PDMS networks. While the analysis of the transverse relation behavior of the dry networks conformed well to the theory of Simon *et al.*, on swelling with a number of solvents more complex behavior was observed. For weakly swollen materials, the parameter q, the extent of averaging of the second moment of the rigid lattice line shape, decreased, however, for strongly swollen networks relaxation became more efficient at short times. This was indicative of increased anisotropy of motion of intercrosslink segments due to deformation of the network. The relationship between molecular weight between crosslinks and the averaging of the second moment thus breaks down in this situation. In summary, while the NMR parameters are very sensitive to swelling ratio, the precise relationship with crosslink density has yet to be clearly defined.

In a number of papers, Cohen-Addad and coworkers [70–74] extended these concepts by describing a scale-invariant model of polymer chain motion. In this model, the local conformations of the chain are partially averaged resulting in a coarse-scale structural unit. If the scale is sufficiently coarse, the statistical properties of the polymer chains are simplified and indeed may be modeled satisfactorily with Gaussian random processes. Within this model the residual dipolar couplings are scaled by the inverse of the number of segments within the coarse-scale structural unit [29]. Brereton further developed this thinking by describing methods for determining statistical averages of the dipolar couplings, considering the motion of a Rouse chain [75] and further the effects of constraints induced by the presence of crosslink points within a network [76].

As a principal experimental tool, Cohen-Addad and coworkers have used extensively the measurement of the so-called pseudosolid echo [77,78], which measures the fluctuating residual dipole–dipole energy of anisotropically reorientating chain segments. As an example of the application to networks, the kinetics of crosslinking of poly(ethylene) by a free radical initiator were measured in real time [79]. The pseudosolid echo decay curve was decomposed into two decays, corresponding to the decays for the uncrosslinked material and the fully crosslinked polymer, respectively. The proportion of the decay due to the crosslinked material was seen to increase in proportion with the gel content.

As discussed recently by Kimmich and Fatkullin [80], a number of experimental approaches have been adopted to measure the residual dipolar coupling in dynamic polymer systems including networks. In addition to the approaches mentioned above, a number of workers have exploited the dependence of the development of double quantum coherence on the strength of the dipolar coupling [81–84]. As described by Spiess and coworkers [82–84], the residual dipolar coupling is proportional to the dynamic order parameter, which is in turn related as above to the inverse of the number of statistical chain segments between constraints. The time evolution of the double quantum coherence can be analyzed directly to determine the dynamic order parameter. Saalwachter and coworkers [81,85,86] have found that a distribution of order parameters is required to provide a satisfactory description of the experimental data. In their study of PDMS networks [81,85], these authors, for example, reported a largely unchanged dynamic order parameter on swelling of the network, but rather a broadening of the distribution function. This is seen as evidence of topologically constrained heterogeneities within the swelling network; this concept is expanded upon and supported by computer simulation in a following paper [86]. As a final comment in this section, it should be noted that the use of CP techniques allows ^{13}C observation and simultaneous measurement of either the residual homonuclear [87] or heteronuclear dipolar interactions [29,88,89].

Summary

The use of modern NMR techniques to determine the chemical and physical structure of polymer networks has been reviewed. On formation of a polymer network, or indeed within an entangled polymer melt, homo- and heteronuclear dipolar couplings are no longer fully averaged by random molecular fluctuations. The resultant changes in the NMR linewidths must be dealt with if accurate assessment of chemical structure is to be achieved. On the other hand, measurement of the residual dipolar order within the network allows estimation of network parameters, such as the number of segments between crosslink points and network order parameters.

^{1}H CRAMPS NMR of Polypeptides in the Solid State

Akira Shoji
Department of Biological Sciences, Gunma University, Tenjin-cho,
Kiryu-shi, Gunma 376-8515, Japan

Introduction

The research of the solid high-resolution NMR rapidly developed recently, and the cross-polarization–magic-angle spinning (CP-MAS) method is most commonly used for the ^{13}C and ^{15}N NMR measurements of organic compounds in the solid state. Very recently, the solid high-resolution proton NMR research developed [1–7] because both quality and quantities are high for the potential of information of the hydrogen nucleus. Study example of solid secondary structure (main-chain conformation) of polypeptide is introduced on the basis of the proton chemical shift this-focus. Therefore, the author introduces the research result of recent proton combined rotation and multiple pulse spectroscopy (CRAMPS) NMR of polypeptides in this chapter. In the attractiveness, the proton CRAMPS NMR research has just begun yet, and it has a further unprecedented possibility of developing in future. This review is the happiness, if it is useful for the future of your scientific research.

Experimental Evidence

Conformational Study of Synthetic Polypeptides by ^{1}H CRAMPS NMR

"Can ^{1}H NMR become an effective means for conformational analysis of polypeptides and proteins in the solid state?" In order to answer this question, the author focus and discuss about the study on correlation between the ^{1}H chemical shift and the main-chain conformation (secondary structure) of synthetic polypeptides [2,4,7]. It is well known that the right-handed α-helix (α-helix), antiparallel β-sheet (β-sheet) and parallel β-sheet (β_P-sheet) forms are the most famous conformations in proteins. In addition, the left-handed α-helix (α_L-helix), polyglycine I (PGI) and II (PGII), polyproline I (PPI) and II (PPII), and left-handed ω-helix (ω_L-helix) conformations are known in synthetic model polypeptides. If the conformational determination of solid polypeptides based on the solid high-resolution ^{1}H NMR is possible, we would obtain the very powerful means in the conformational analysis of proteins. Shoji and coworkers [1–7] have extensively studied for this work with various kinds of synthetic polypeptides and some cyclic dipeptides. Using these samples adopting the characteristic differences in conformation, they challenged to systematically test the power of ^{1}H CRAMPS NMR for the structural analysis in the solid state.

Conformational Analysis of Polypeptides based on α-Proton Chemical Shifts

α-Helix and β-sheet Forms. Figure 1-(1) shows the ^{1}H CRAMPS NMR spectra of poly(L-alanines) (PLAs) in the solid state [1,2]: (A) H-[Ala]$_8$-NHBu (β-sheet form), (B) [Ala]$_n$ − 1 (mixture of α-helix and β-sheet forms), and (C) [Ala]$_n$ − 5 (α-helix form). Each proton signal can be easily assigned to NH (7–10 ppm), H^α (3–6 ppm), and H^β (0–2 ppm) from downfield. From these spectra, it is found that (1) ^{1}H chemical shift of the H^α signal is significantly different and conformation-dependent [α-helix (3.9 ppm) and β-sheet (5.1 ppm)]; (2) ^{1}H chemical shift of the H^β signal is nearly the same (1.2–1.4 ppm) within the error limit at the present resolution; and (3) H^N signal is broad due to residual dipolar coupling between amide ^{1}H and quadrupolar ^{14}N nuclei [8]. This fact confirms the view that the main cause of the ^{1}H chemical shift displacement is not by the degree of polymerization but by the conformation of polypeptides. Thus, the chemical shift of the H^α signal in the α-helix PLA is to low frequency by 1.2 ppm from that in the β-sheet, indicating that the H^α signal is a useful fingerprint for conformational analysis of PLA in the solid state.

Figure 1-(2) shows the ^{1}H CRAMPS NMR spectra of poly(L-valines); (A) [Val]$_n$ − 1 (DP$_n$ is about 5, β-sheet form) and (B) [Val]$_n$ − 5 (DP$_n$ is about 100, β-sheet) in the solid state. It is confirmed that the ^{1}H chemical shift of the H^α signal does not depend on the degree of polymerization because the stable conformation of PLVs used here is the β-sheet form alone and it does not change with increasing molecular weight. Thus, the ^{1}H chemical shifts of the H^α, H^β, and H^γ signals are also independent of the degree of polymerization (β-sheet form). This fact confirms the view that the main cause of the ^{1}H chemical shift displacement is not the degree of polymerization but the conformation of polypeptides.

For the case of poly(L-leucines) (PLLs), it is obvious that the chemical shift of the H^α signal is

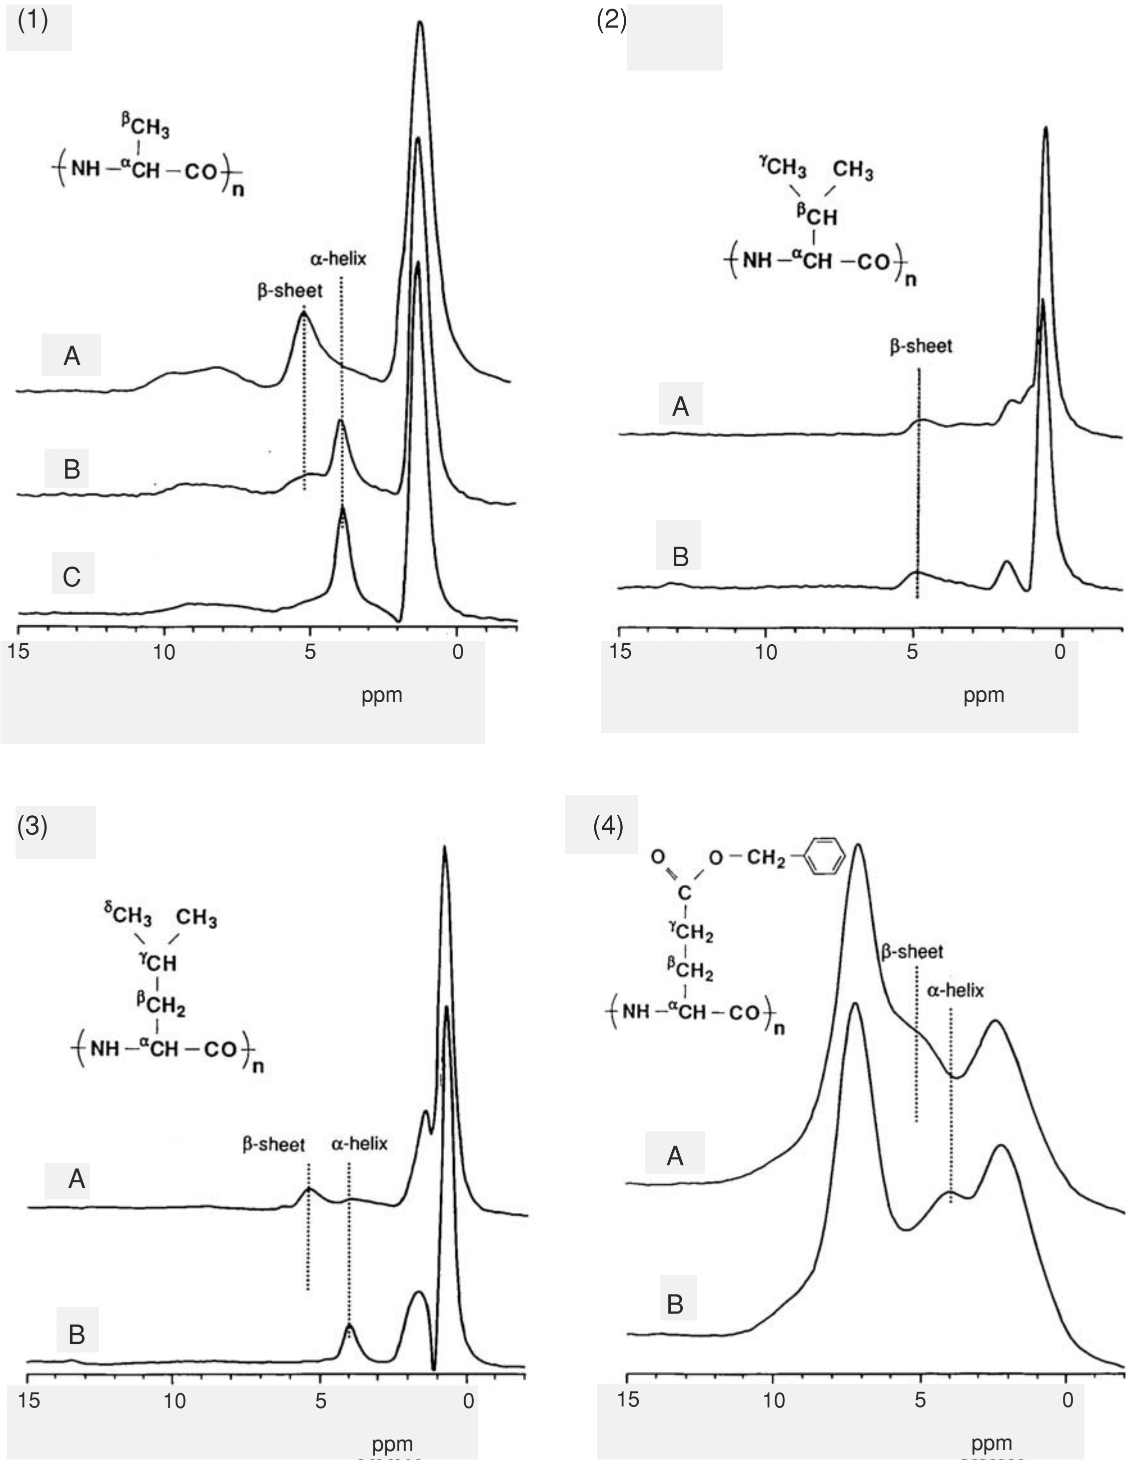

Fig. 1. NMR spectra (300 MHz ^{1}H CRAMPS) of (1) poly(L-alanines): (A) H-[Ala]$_8$-NHBu (β-sheet form), (B) [Ala]$_n - 1$ (DP$_n \approx$ 16, α-helix + β-sheet), and (C) [Ala]$_n - 5$ (DP$_n \approx$ 65, α-helix); (2) poly(L-valines): (A) [Val]$_n - 1$ (DP$_n \approx$ 5, β-sheet form) and (B) [Val]$_n - 5$ (DP$_n \approx$ 100, β-sheet); (3) poly(L-leucines): (A) [Leu]$_n - 1$ (β-sheet) and (B) [Leu]$_n - 2$ (α-helix); and (4) poly(γ-benzyl-L-glutamates): (A) H-[Glu(OBzl)]$_6$-OBzl (β-sheet) and (B) [Glu(OBzl)]$_n$ (α-helix).

conformation-dependent [α-helix: 4.0 ppm, β-sheet: 5.5 ppm], as shown in Figure 1-(3). The ^{1}H chemical shifts of the side-chain signals are almost conformation-independent, and the H^N signal is so broad as to be almost undetectable. This NMR feature is basically quite similar to that of PLA. It is especially noteworthy that the ^{1}H chemical shift region of the H$^\alpha$ signal is fully separated from that of the side-chain signals, in spite of the fact that the L-leucine residue has a bulky side group. Therefore, the ^{1}H chemical shift of the H$^\alpha$ signal is very useful for conformational analysis of polypeptides in the solid state.

Furthermore, for the case of poly(γ-benzyl-L-glutamate) (PBLG), which has side-chain benzyl esters, the ^{1}H NMR signals are roughly classified into three regions (amide, phenyl, and benzyl H; H$^\alpha$; H$^\beta$, and H$^\gamma$ signals), as shown in Figure 1-(4). This is also similar to the case of PLA and PLL, whereas the ^{1}H NMR signals become broader over the wide range of chemical shifts. Accordingly, it is possible to recognize that the ^{1}H chemical shift of the H$^\alpha$ signal is conformation-dependent [α-helix (4.0 ppm) and β-sheet (nearly 5.2 ppm)]. The chemical shift of the H$^\alpha$ signal in the α-helix is to low frequency by 1.2 ppm compared with that in the β-sheet form, which is quite reasonable.

The ^{1}H chemical shift data of the samples used here are summarized in Table 1, together with their characteristics of the samples.

In conclusion, the chemical shift of the H$^\alpha$ signal is important and very useful for conformational analysis of polypeptides in the solid state because the ^{1}H chemical shift region of the H$^\alpha$ signal is fully separated with that of the side-chain signals (except for threonine H$^\beta$ residue alone in solution).

Polyglycine (PGI and PGII) and poly(L-proline) (PPI and PPII) forms. Figure 2-(1) shows the ^{1}H CRAMPS NMR spectra of polyglycines (PGs): (A) PGI and (B) PGII forms [6]. It is admitted that PGI (antiparallel β-sheet) and PGII (intermolecular hydrogen-bonded 3_1-helix) forms are stable in the solid state [9]. The ^{1}H chemical shifts of the H$^\alpha$ signals ($\delta = 4.3$, PGI; $\delta = 3.7$, PGII) depend on main-chain conformation. That is, the chemical shift of the H$^\alpha$ signal of PGI is to high frequency by 0.6 ppm

Table 1: ^{1}H and ^{13}C chemical shifts and characteristics of polypeptides and cyclic dipeptides

Sample	DP$_n$[*]	Conformation[†]	H$^\alpha$	H$^\beta$	C=O	C$^\alpha$	C$^\beta$

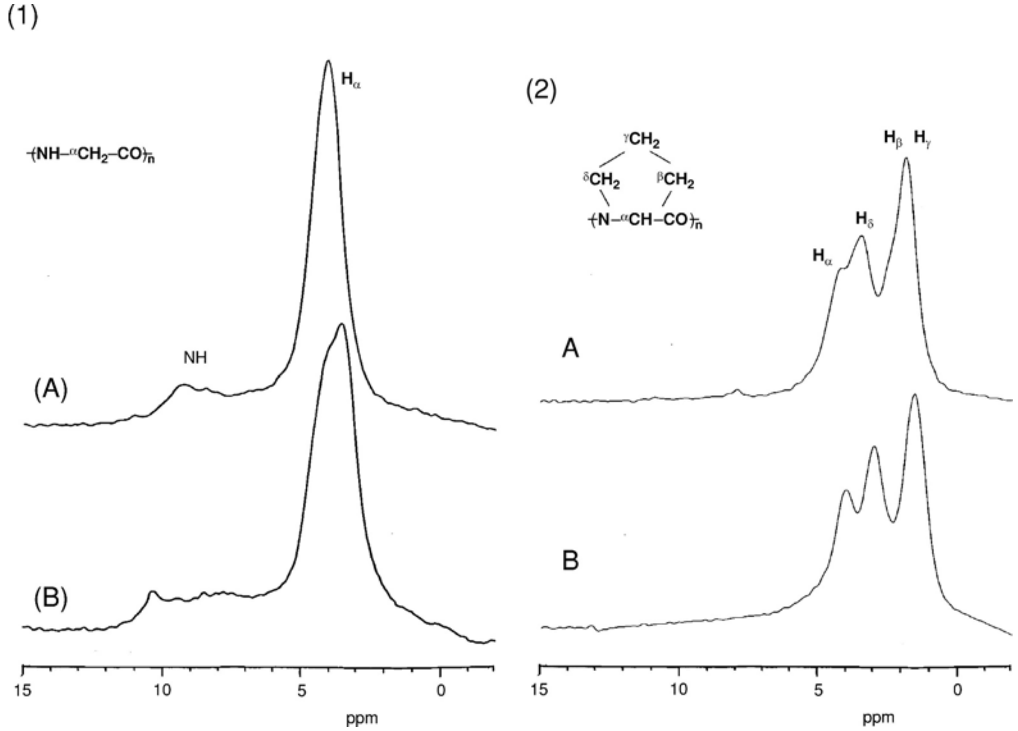

Fig. 2. NMR spectra (300 MHz ^{1}H CRAMPS) of (1) polyglycines: (A) PGI (polyglycine I) and (B) PGII (polyglycine II); (2) poly(L-prolines): (A) PPI (polyproline I) and (B) PPII (polyproline II).

from that of the PGII. This indicates that the chemical shift of the H^α signal is useful for conformational analysis of solid PG, whereas the chemical shift difference of the H^α signal is relatively small between PGI and PGII forms.

In addition, it has been found that the ^{1}H chemical shift of the H^α signal of PGI (β-sheet) is to low frequency by 0.6–1.2 ppm from those of other β-sheet polypeptides such as PLA, PLV, PLL, and PBLG. From the standpoint of the ^{1}H chemical shifts, glycine residue is a special α-amino acid compared with other common α-amino acids, and it contains no asymmetric carbon atom, which is very convenient for the conformational analysis of polypeptides and proteins. However, we should carefully pay attention to the H^α chemical shifts of glycine residue because the H^α chemical shifts of both PGI and PGII are near to that of the α-helix (3.9–4.0 ppm). Therefore, it is noteworthy that the ^{1}H chemical shift of PG is very useful in assigning the H^α signal from other common α-amino acid residues and in analyzing the main-chain conformation of silk fibroins and collagen fibrils.

On the other hand, the proline residue does not have amide proton, and therefore it cannot form $N–H\cdots O=C$ hydrogen bonding. For this reason, however, the proline residue fits in a unique structure, and PPII is also an important basic structure found in collagen as well.

Figure 2-(2) shows the ^{1}H CRAMPS NMR spectra of poly(L-prolines) (PPs). From Figure 2-(2), it is deduced that the chemical shift of the H^α signal is almost the same ($\delta = 4.2$, PPI; $\delta = 4.0$, PPII). In contrast, the chemical shift of the H^δ signal is significantly conformation-dependent ($\delta = 3.6$, PPI; $\delta = 3.0$, PPII), suggesting that this peak is a useful fingerprint for conformational analysis of PP in the solid state. It is the first case in which the ^{1}H chemical shifts of the side-chain protons depend significantly on the main-chain conformation of the PP, but the main-chain H^α does not depend on the conformation. To confirm the assignment of individual ^{1}H signals in conformational analysis, it is promising to apply the two-dimensional (2D) ^{1}H–^{13}C heteronuclear correlation (HETCOR) NMR measurement [6,10–13]. In the case of PP, it is easy to separate the individual ^{1}H peaks of PPs on the basis of the well-resolved ^{13}C signals because the ^{1}H–^{13}C correlations are clear in the 2D spectra for ^{1}H–^{13}C pairs (figure not shown).

Comparison of the ^{1}H Chemical Shift Data of Amino Acid Residues in the Solid State and in Solution

It is very important to compare the ^{1}H chemical shift data in the solid state with those in solution, especially for the H$^\alpha$ chemical shift. According to the solution ^{1}H NMR data summarized in the references [14–16], it is possible to estimate the chemical shift value of the H$^\alpha$ signal in the α-helix and β-sheet forms in solution. They can be concretely determined by the addition of -0.38 ppm (α-helix) and 0.38 ppm (β-sheet) to the H$^\alpha$ value in the random coil state, which has been determined in solution measurements [14]. However, the experimental differences of the ^{1}H chemical shifts are present between in solid state and in solution. In the α-helical polypeptides, the H$^\alpha$ chemical shifts measured in the solid state (3.9–4.0 ppm) are identical with those in the solution data (3.94–3.95 ppm), whereas in the β-sheet polypeptides the H$^\alpha$ chemical shifts measured in the solid state (4.9–5.5 ppm) are 0.2–0.8 ppm to high frequency from those estimated in the solution data (4.70–4.71 ppm) [14]. This comparison shows a very interesting and important finding. It is not a reason to estimate H$^\alpha$ chemical shifts of β-sheet polypeptides in solution, according to the method described above. However, it does highlight that more careful attention must be given to determining the ^{1}H chemical shifts of the β-sheet polypeptides using the solution data proposed by Wishart *et al.* [14–16].

Conformational Study of Cyclic Dipeptides by ^{1}H CRAMPS NMR: Cyclo(L-alanyl-L-alanyl) and cyclo(L-alanyl-D-alanyl)

It is known that the ring conformation of cyclo[L-Ala-L-Ala] (LL) is a boat form (C$^\beta$: equatorial) and that of cyclo[L-Ala-D-Ala] (LD) is a planar form in the solid state by X-ray crystal diffraction analysis [17]. Figure 3 shows the ^{1}H CRAMPS NMR spectra of cyclic dipeptides, (A) LL and (B) LD in the solid state [2,18,19]. It is found that (1) the chemical shift of the H$^\alpha$ signal is different between LL (4.3 ppm) and LD (4.7 ppm), (2) the chemical shifts of the H$^\beta$ signals are almost identical for LL and LD (1.4–1.5 ppm), and (3) the chemical shift of the amide ^{1}H signal is quite different between LL (10.3 ppm) and LD (9.3 ppm). The chemical shift difference of the H$^\alpha$ signal can be attributed mainly to the differences in ring conformation in the solid state. The chemical shift difference of the amide ^{1}H signal between LL and LD may be explained by considering an intermolecular hydrogen-bonding effect as well as its ring conformation.

This interpretation is compatible with the X-ray crystal diffraction analysis by Sletten [17]. As shown in Figure 1, in general, the true amide ^{1}H chemical shift cannot be determined exactly using any natural abundant polypeptides. It is noteworthy that the ^{1}H signal line shape directly bonded to ^{14}N of LL and LD exhibits symmetric singlet pattern in spite of the heteronuclear dipolar interaction between quadrupolar ^{14}N nuclei and amide protons. Thus, it is valuable to determine true amide ^{1}H chemical shift in this series, and the ^{15}N-labeled LL and LD samples are needed for the future work. In addition, it is important to clarify the relation between the ^{1}H chemical shift and the ring conformation (such as the planar, boat equatorial, boat axial, and chair forms) in the solid state by ^{1}H CRAMPS NMR.

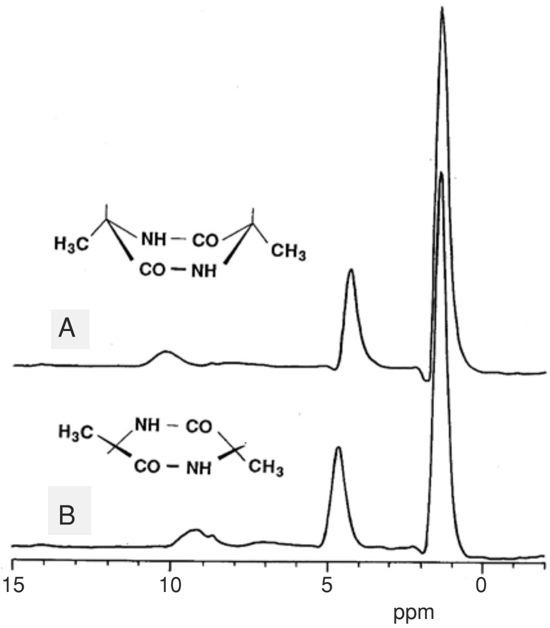

Fig. 3. NMR spectra (300 MHz ^{1}H CRAMPS) of cyclic dipeptides: (A) cyclo[L-Ala-L-Ala] (LL) and (B) cyclo[L-Ala-D-Ala] (LD).

Conformational Study of Specific Deuterium-labeled Polypeptides by ^{1}H CRAMPS NMR

It is valuable to test the advantages of specific deuterium labeling of polypeptides in the solid state. In general, specific isotope labeling is a very powerful tool to aid assigning complicated signals. The NMR method utilizes isotope labeling to advantage, proton signals often overlap each other on ^{1}H CRAMPS NMR spectra because the resolution is not good. In such cases, a specific deuterium labeling technique sometimes enables one to observe separately only a specific proton and to eliminate all other unnecessary ^{1}H peaks.

Figure 4 shows the ^{1}H CRAMPS NMR spectra of α-helix PBLGs: (A) [Glu(OBzl)]$_n$ (natural abundance), (B) [Glu(OBzl)]$_n$-d_2 (γ-protons deuterated), and (C) [Glu(OBzl)]$_n$-d_7 (benzyl protons deuterated) [20,21].

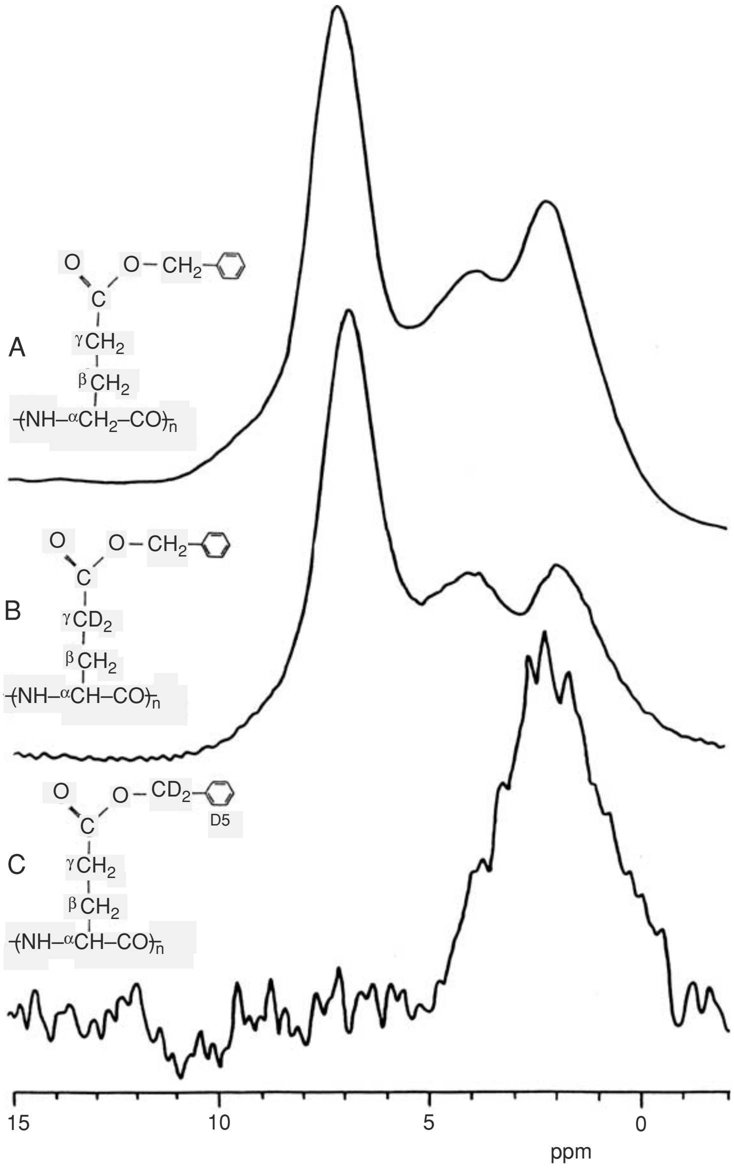

Fig. 4. NMR spectra (300 MHz ^{1}H CRAMPS) of poly(γ-benzyl-L-glutamates): (A) $[\text{Glu(OBzl)}]_n$ (natural abundance, powder), (B) $[\text{Glu(OBzl)}]_n$-d_2 (γ-protons deuterated, film prepared from the chloroform solution), and (C) $[\text{Glu(OBzl)}]_n$-d_7 (benzyl protons deuterated, film prepared from the $CHCl_3$ solution).

It is evident that the signal intensity at 2.2 ppm of $[\text{Glu(OBzl)}]_n$-d_2 (B) is lower than that of $[\text{Glu(OBzl)}]_n$ (A), and H^γ signal of $[\text{Glu(OBzl)}]_n$-d_7 has fully disappeared. This shows that specific deuterium labeling is useful for removing a specific proton signal from the overlapping signals of polypeptides in ^{1}H CRAMPS NMR spectra. In contrast, it is recognized that the signals of all benzyl protons are clearly removed in deuterated samples of the benzyl group $[\text{Glu(OBzl)}]_n$-d_7 (C) but the signal-to-noise (S/N) ratio and the resolution are not sufficient, as shown in Figure 4. Thus, deuterium labeling in ^{1}H CRAMPS spectra is useful for exact assignment and removing the specific signals, if the amount of deuterium substitution is not great and the resolution is sufficient to get a good spectrum.

Application of ^{1}H CRAMPS NMR to Conformational Study of Natural Fibrous Proteins and their Model Polypeptides

It was shown, in a previous section, that the conformation of solid polypeptides can be determined based on the ^{1}H chemical shift. In this section, the structural analysis of a fibrous protein (silk fibroins) in the solid state will be described. It usually happens that time some ^{1}H signals overlap each other in silk fibroins due to the resolution limit of ^{1}H CRAMPS. This may be solved partly by improvement of the resolution limit in ^{1}H CRAMPS using 2D ^{1}H–^{13}C HETCOR [1,6,10–13], which is useful for improving the practical value of CRAMPS for the conformational analysis of proteins.

It is anticipated that the ^{1}H chemical shifts of a more simplified model polypeptide such as $[\text{Ala-Gly}]_{12}$ will be a good guide to the model for the assignment of the NMR spectra of these silk fibroins in the solid state [6,7,22].

Conformational Study of Silk Fibroins by ^{1}H CRAMPS NMR

Figure 5 shows the ^{1}H CRAMPS NMR spectra of two silk fibroins: (A) *Bombyx mori*-I (silk I form) and (B) *Bombyx mori*-II (silk II form) fibroins [6,7]. They give highly resolved ^{1}H CRAMPS NMR spectra in the solid state, which are the first high-resolution solid state ^{1}H CRAMPS NMR spectra of such natural protein.

It should be noted that the amino acid sequence (primary structure) of these two samples is completely identical, but their main-chain conformations are different [6,7,22–24]. As expected, these two conformations are quite different to each other in terms of ^{1}H CRAMPS NMR spectra. The H$^\alpha$ signals of *Bombyx mori*-I (silk I) and *Bombyx mori*-II (silk II) showed a singlet ($\delta = 3.9$) and doublet ($\delta = 5.0$ and 3.9), respectively. In addition, the chemical shift of the H$^\beta$ protons (mainly from L-alanine residues) of *Bombyx mori*-I ($\delta = 1.6$) is different from that of *Bombyx mori*-II ($\delta = 1.2$). It is clear in this case that the chemical shifts of side-chain protons depend on the conformation, i.e. silk I and II. This is a very important result because it is confirmed that the ^{1}H chemical shifts of the side chains in polypeptides are principally conformation-dependent. In conclusion, the chemical shifts of the H$^\alpha$ and side-chain H$^\beta$ signals are useful for conformational analysis of *Bombyx mori* silk fibroins in the solid state, and thus, the ^{1}H CRAMPS NMR is a useful tool for conformational analysis of silk fibroins in the solid state.

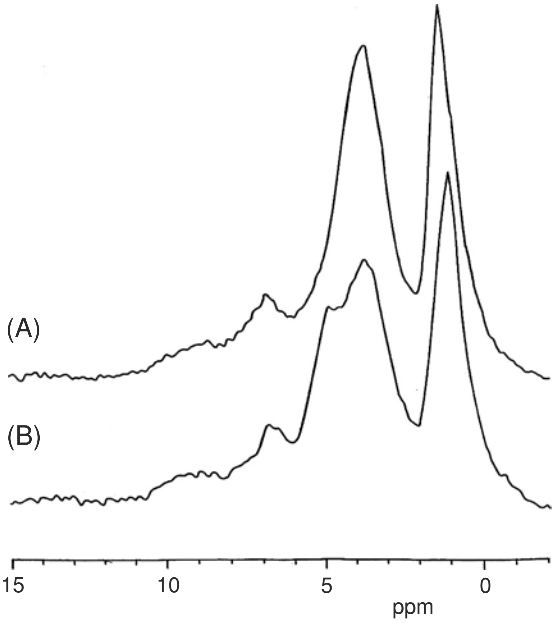

Fig. 5. NMR spectra (300 MHz ^{1}H CRAMPS) of silk fibroins (64 scans): (A) *Bombyx mori*-I (silk I form) and (B) *Bombyx mori*-II (silk II form). Peak assignment: H^N, 10–8 ppm; side-chain phenyl, 6.9 ppm; H$^\alpha$, 3.9–5.0; side chain, 1.6–1.2 ppm.

Two-dimensional ^{1}H–^{13}C HETCOR NMR Study of Silk Fibroins

It is possible to separate and assign the ^{1}H signals of the polypeptides and silk fibroins using 2D HETCOR spectra because the correlations are clearly resolved in the 2D spectra for proton–carbon pairs.

Figure 6 shows the 2D ^{1}H–^{13}C HETCOR NMR spectra of silk fibroins: (A) *Bombyx mori*-I (silk I) and (B) *Bombyx mori*-II (silk II) in the solid state [6]. Individual ^{1}H signals can be easily assigned on the basis of the corresponding ^{13}C signals. As shown in Figure 6, it can be admitted that the H$^\alpha$ signals of the glycine and L-alanine residues overlap in *Bombyx mori*-I, but that the H$^\alpha$ signal of the glycine residue is distinguished from that of the L-alanine residue in *Bombyx mori*-II. Furthermore, we can detect the H$^\alpha$ and H$^\beta$ peaks of L-serine residue at around 1.5–2.5 ppm in 2D spectra, although the L-serine content is very low compared with the L-alanine or glycine content in *Bombyx mori*.

Thus, the 2D HETCOR technique allows the resolution of ^{1}H CRAMPS to be tied to the higher resolution associated with ^{13}C chemical shifts.

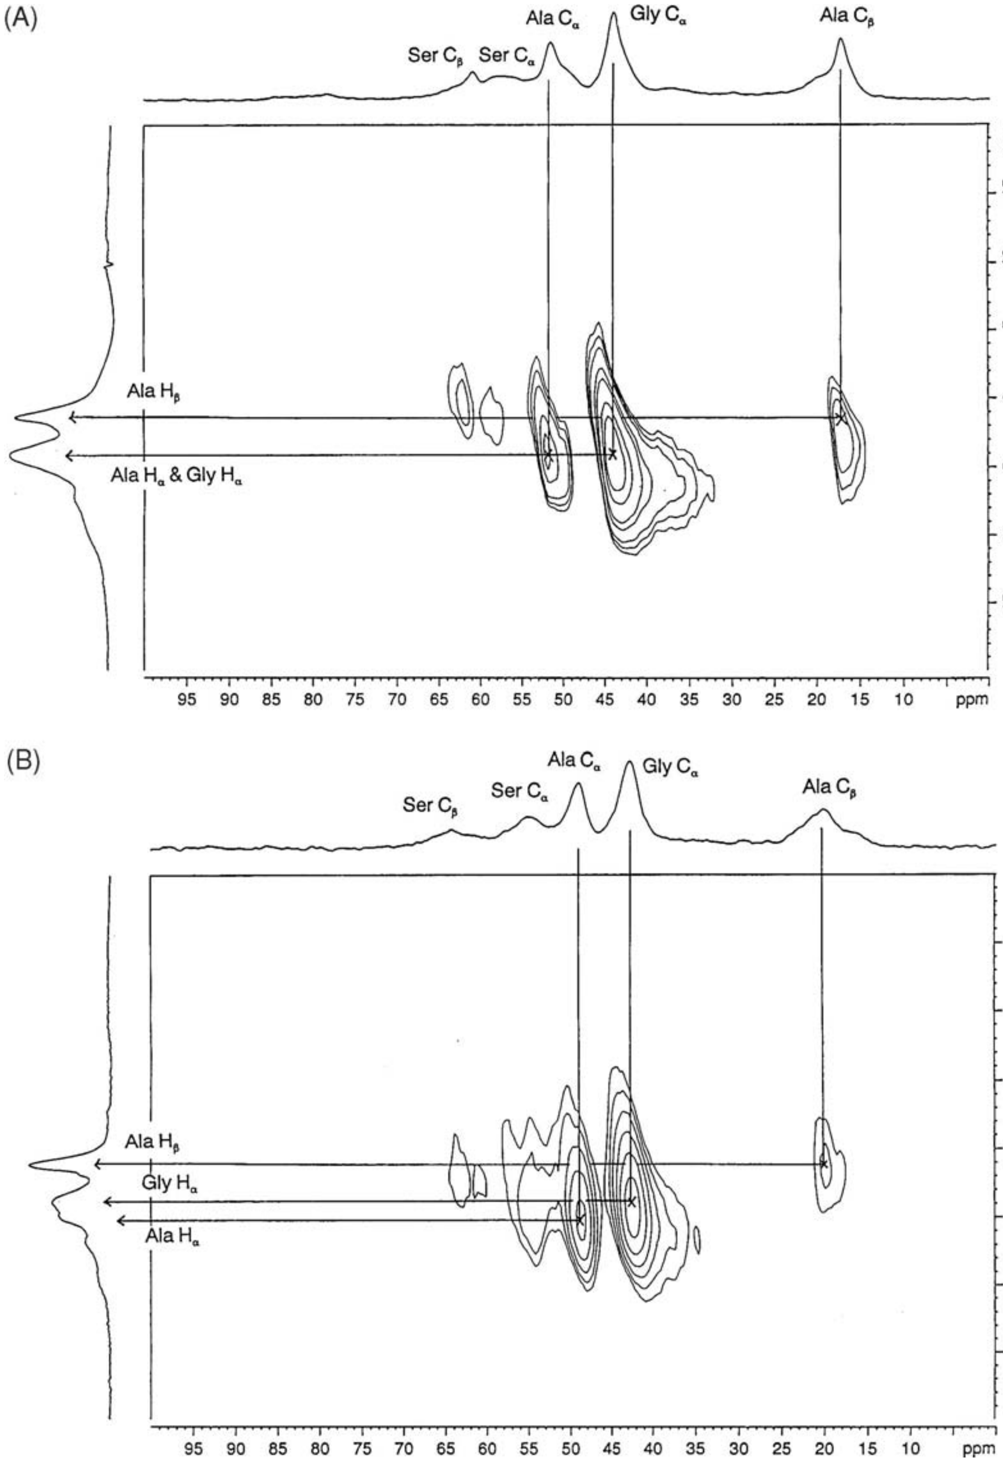

Fig. 6. NMR spectra (2D ^{1}H–^{13}C HETCOR) of silk fibroins: (A) *Bombyx mori*-I (silk I) and (B) *Bombyx mori*-II (silk II).

^{1}H CRAMPS and 2D ^{1}H–^{13}C HETCOR NMR Studies of Silk Fibroin Model Polypeptide

2D HETCOR NMR has the disadvantage of having a small scaling factor, which leads to a larger error for ^{1}H chemical shifts. Accordingly, it is necessary to confirm the observation mentioned above with a well-defined simple model polypeptide of *Bombyx mori* [Ala-Gly]$_{12}$.

Figure 7 shows the 2D ^{1}H–^{13}C HETCOR NMR spectra of well-defined poly(L-alanyl-glycines), (A) [Ala-Gly]$_{12}$-I (silk I) and (B) [Ala-Gly]$_{12}$-II (silk II), in the solid state. As expected, it was induced from the spectra that the H$^\alpha$ signals of L-alanine and glycine residues overlapped ($\delta = 3.6$) and gave a single peak in [Ala-Gly]$_{12}$-I, but that the H$^\alpha$ chemical shift of the L-alanine residues in [Ala-Gly]$_{12}$-II is to high frequency from that of the glycine residues, and they are separated (doublet). The ^{1}H and ^{13}C chemical shifts and conformational characteristics of natural silk fibroin and its model polypeptide samples are shown in Table 2.

These results indicate that the H$^\alpha$ chemical shift of L-alanine residue is almost the same as that of glycine residue in the silk I form for [Ala-Gly]$_{12}$-I and *Bombyx mori*-I. This tendency agrees well with the result obtained from 2D HETCOR spectra of *Bombyx mori*-I and [Ala-Gly]$_{12}$-I. The most interesting result is that the H$^\alpha$ chemical shift of the glycine residue does not change between silk I and II forms (in both *Bombyx mori* and [Ala-Gly]$_{12}$), whereas that of the L-alanine residue shows apparent conformation dependency. Thus, the H$^\alpha$ chemical shift of Ala and Gly residues may offer the key information to clarify the silk I and II structures. In addition, the H$^\beta$ chemical shift of [Ala-Gly]$_{12}$-II agrees completely with that of PLA adopting a β-sheet form. These results show that the ^{1}H chemical shifts of the well-defined model polypeptide are useful for the structural analysis of silk fibroins in the solid state.

It maybe anticipated that the well-defined [Ala-Gly]$_{12}$ plays an important role for determination of unsolved silk I structure.

Determination of Amide Proton Chemical Shift

Observation of the Amide Proton (H^N) Signal of ^{15}N-labeled PLAs

Recently, the problem of a very broad amide proton (H^N) signal was solved and the true H^N chemical shift was determined [4]. It is known that H^N signal broadening is caused by the residual dipolar couplings between the quadrupolar ^{14}N nuclei and the amide protons. The ^{1}H–^{14}N dipolar coupling causes an asymmetric doublet pattern, which disturbs the determination of the true H^N chemical shift in the ^{1}H NMR spectra [1,2,4]. Such a dipolar broadening has never been observed in solution NMR because the dipolar coupling is averaged out by the rapid molecular motion.

The solution to how to get a sharp and normal H^N signal and how to determine the true H^N chemical shift of solid polypeptides is demonstrated. Shoji *et al.* used the fully ^{15}N-labeled (99 at.%) polypeptides such as poly(L-alanine-^{15}N) ([Ala*]$_n$) and poly(L-leucine-^{15}N) ([Leu*]$_n$), and successfully determined the true H^N chemical shift of these polypeptides adopting the α-helix and β-sheet forms.

Figure 8 shows the ^{1}H CRAMPS spectra of ^{15}N-labeled PLAs using the MREV-8 pulse sequence at 3.5 kHz MAS speed: (A) [Ala*]$_n$ − 2 (99 at.% purity of ^{15}N, α-helix) and (B) [Ala*]$_n$ − 1 (99 at.% purity of ^{15}N, β-sheet) in the solid state [4].

It is obvious that the line shape of the ^{15}NH proton signal of [Ala*]$_n$ − 2 and [Ala*]$_n$ − 1, in which the quadrupolar effect is absent, exhibits a normal symmetric singlet pattern. Thus, it is apparent that the quadrupolar ^{14}N nuclei is responsible for the signal broadening, and that the asymmetric line shape of the ^{14}NH proton peak, aside from the ^{15}NH proton signal, is still broad relative to the H$^\alpha$ and H$^\beta$ signals. From the ^{1}H CRAMPS NMR spectra, therefore, it was able to determine the true H^N chemical shift values for [Ala*]$_n$ − 2 (α-helix; $\delta = 8.0$) and [Ala*]$_n$ − 1 (β-sheet; $\delta = 8.6$) under MAS speed of 3.5 kHz. This is the first determination of the true H^N chemical shifts of PLAs by the ^{1}H CRAMPS NMR.

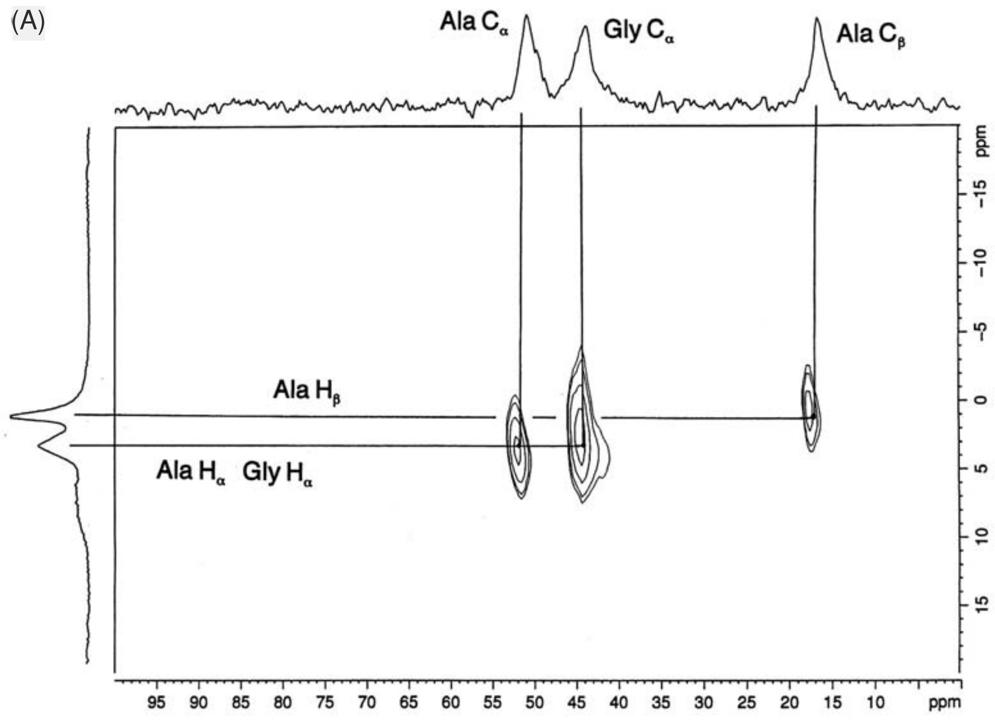
Similarly, the true NH chemical shifts of PLLs were determined using fully ^{15}N-labeled samples under MAS speed of 3.5 kHz and their chemical shifts depend on conformation (α-helix: $\delta = 8.1$; β-sheet: $\delta = 9.1$) [4]. The ^{1}H chemical shift data and conformational characteristics of these samples are summarized in Table 3.

Therefore, the ^{1}H CRAMPS method is a very useful tool for the determination of the ^{15}NH proton chemical shifts of solid polypeptides.

Correlation between the Amide ^{1}H Chemical Shift and Main-chain Conformation

According to X-ray diffraction studies of PLAs by Arnott *et al.* [25,26], the distance between the nitrogen and oxygen atoms was 2.83 and 2.87 Å for the β-sheet and α-helix forms, respectively. Accordingly, the true H^N proton chemical shifts of [Ala*]$_n$ − 1 (β-sheet) appear to be high frequency by comparison with that of [Ala*]$_n$ − 2 (α-helix), which is qualitatively acceptable.

Next, it is interesting to compare the ^{1}H chemical shift results of polypeptides in the solid state with those in solution [14–16], attention being given to the dependence of the amide proton chemical shifts on conformation. The following results are obtained: (1) the amide proton chemical shifts of the α-helical polypeptides in the solid state (8.0–8.2 ppm) are identical with those in solution (7.96–8.04 ppm) and (2) the amide proton chemical shifts of the β-sheet polypeptides in the solid state (8.6–9.1 ppm)



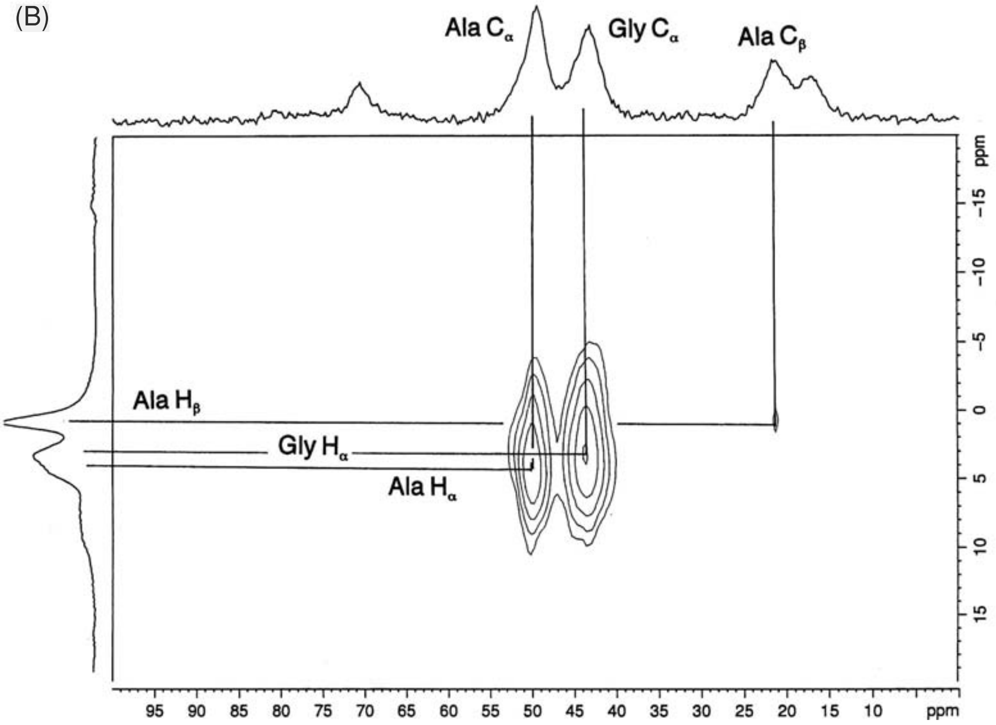


Fig. 7. Spectra (2D ^{1}H–^{13}C HETCOR) of [Ala-Gly]$_{12}$: (A) [Ala-Gly]$_{12}$-I (silk I) and (B) [Ala-Gly]$_{12}$-II (silk II). Peak assignment: H^N, 10–8 ppm; H^α, 5.0–3.6 ppm; and H^β, 1.2–1.5 ppm.

Table 2: ^{1}H and ^{13}C chemical shifts, and conformational characteristics of silk fibroin and its model polypeptide sample

Sample	Conformation*	H^{α}	H^{β}	C=O	$C^{\alpha\dagger}$	$C^{\beta\ddagger}$
Bombyx mori-I	Silk I	3.9	1.6	177.2, 171.2	51.7, 44.1	17.3
Bombyx mori-II	Silk II	5.0, 3.9	1.2	172.6, 170.2	49.2, 42.9	20.2
$[\text{Ala-Gly}]_{12}$-I	Silk I	3.6	1.5	177.4, 170.6	51.3, 43.9	17.2
$[\text{Ala-Gly}]_{12}$-II	Silk II	5.0, 3.6	1.2	173.2, 169.8	49.6, 43.4	21.5

$[\text{Ala-Gly}]_{12}$, well-defined poly(L-alanyl-glycine) (24mer); *Bombyx mori* (silk fibroin).
*Conformations of these samples were determined by ^{13}C and ^{15}N CP-MAS NMR and IR spectroscopic methods.
$^{\dagger 13}$C chemical shifts of α-carbons of L-alanine and glycine residues.
$^{\ddagger 13}$C chemical shift of β-methyl carbon of alanine residue.

are 0.1–0.6 ppm to high frequency from those in solution (8.44–8.52 ppm). These chemical shift displacements of the ^{15}NH protons are very similar to those of the H^{α} protons for PLAs and PLLs. These results are quite interesting findings and the main reason for the chemical shift difference between solid state and solution can be explained by a solvent effect in the solution.

In conclusion, it is certified that the ^{15}NH proton chemical shift is a useful index for conformational analysis and to distinguish the hydrogen bond characteristics of polypeptides in the solid state.

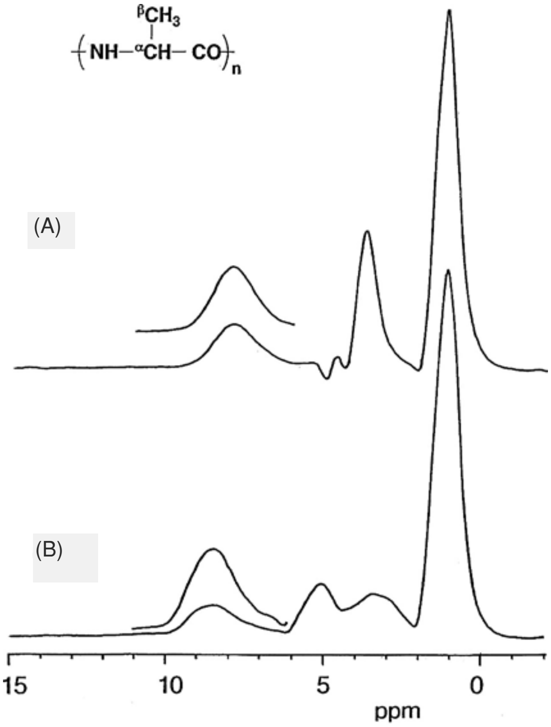

Fig. 8. NMR spectra (300 MHz ^{1}H CRAMPS) of α-helical and β-sheet poly(L-alanines) using the MREV-8 pulse sequence at 3.5 kHz MAS speed: (A) $[\text{Ala*}]_n - 2$ (^{15}N-labeled, α-helix) and (B) $[\text{Ala*}]_n - 1$ (^{15}N-labeled, β-sheet). Peak assignment: H^N, 8.6 ppm (β-sheet) and 8.0 ppm (α-helix); H^{α}, 5.0–5.2 ppm (β-sheet) and 3.9–4.2 ppm (α-helix), H^{β}, 1.2 ppm (β-sheet) and 1.4 ppm (α-helix). Note that the additional peaks around 4.0–5.0 ppm in spectra (A) is assigned to career noise signal.

Determination of N–H Bond Length from the Dipolar Spinning Sideband Pattern of the Amide ^{1}H Signals

An accurate determination of the N–H covalent bond length is important for elucidating polypeptide conformations because the N–H bond length directly mirrors the $>\text{N–H}\cdots\text{O}=\text{C}<$ hydrogen bond strength and is responsible for the long range order in the system. The ^{1}H CRAMPS has great potential for this purpose, and it is necessary to examine whether it is effective.

The ^{15}N–^{1}H bond length can be measured by observing the dipolar line width, which is simulated by the ^{15}N–^{1}H dipolar spinning sidebands (SSBs). The ^{15}N–^{1}H dipolar interaction can be estimated directly from the ^{1}H CRAMPS NMR because the ^{1}H chemical shift anisotropy is averaged to zero during the ^{1}H CRAMPS measurement. The N–H bond length of PLA is almost indeterminate by the X-ray diffraction. It is also difficult to determine the N–H bond length using the neutron diffraction because this method needs the deuterium-labeled PLA to be in single crystal state.

Table 3: ^{1}H chemical shifts and conformational characteristics of polypeptides

			^{1}H chemical shift, δ (ppm)			
Sample	A/I†	Conformation‡	$H^{\beta}(+H^{\gamma})$	H^{δ}	H^{α}	H^{N}§
H-[Ala]$_5$-NHBu	—	β-sheet	1.2		5.0	8.4
[Ala]$_n$ − 5	65	α-helix	1.4		3.9	8.2
[Ala*]$_n$ − 1	4	β-sheet	1.2		5.2	8.6
[Ala*]$_n$ − 2	100	α-helix	1.4		4.0	8.0
[Leu]$_n$ − 1	5	β-sheet	0.9	1.5	5.5	—
[Leu]$_n$ − 2	100	α-helix	0.8	1.7	4.0	8.2
[Leu*]$_n$ − 1	5	β-sheet (+α-helix)	0.9	1.6	5.4	9.1
					(4.0)	(8.2)
[Leu*]$_n$ − 2	100	α-helix	0.8	1.6	4.0	8.1

Ala*, ^{15}N-labeled L-alanine; Leu*, ^{15}N-labeled L-leucine.

†A/I corresponds to the theoretical number-averaged degree of polymerization.

‡Conformations were determined by the ^{13}C and ^{15}N CP-MAS NMR, IR, and far-IR spectroscopic methods.

§Amide proton (H^N) chemical shift was obtained using the MREV-8 pulse sequence at 3.5 kHz MAS speed.

¶Containing a small amount of α-helix.

In this section, a new methodology to determine the ^{15}N–^{1}H bond length of fully ^{15}N-labeled PLAs adopting the α-helix and β-sheet forms from the ^{15}N–^{1}H dipolar sideband patterns observed in the ^{1}H NMR spectra [5]. To observe the full spectral width of the dipolar sideband patterns, the quadrature-phase detection (QD) measurement was performed. QD was carried out according to the phase-cycling technique proposed by Burum *et al.* [27], and the MREV-8 pulse sequence was applied. The samples used here are fully ^{15}N-labeled PLAs (99 at.% of ^{15}N purity) [4,5].

Determination of N–H Bond Length

Figure 9 shows the ^{1}H CRAMPS NMR spectra of fully ^{15}N-labeled PLAs for (A) α-helix and (B) β-sheet forms in the solid state. The SSBs of the H^{α} proton and H^{β} proton signals of PLAs are indicated by asterisks (*), and those of the amide proton (H^N) signal by open circle (o). The SSBs of the H^{α} and H^{β} signals fell off rapidly compared to those of the amide protons, whereas those of the H^N signal gradually decreased due to the large ^{15}N–^{1}H heteronuclear dipolar interaction. The N–H dipolar SSB pattern of α-helical PLA is obviously different from that of β-sheet one, as can be seen from Figure 9.

The sideband pattern is sensitive to the N–H bond length and the relative intensity of SSBs to the center peak decreases with longer N–H distance. It is therefore possible to determine the N–H bond length within an accuracy of 0.01 Å by careful comparison of the integral ratio of the center peak to the sideband intensities of the dipolar spectrum obtained experimentally with that of the simulated spectra.

Thus, it is successfully determined that the N–H bond length for PLAs were 1.09 and 1.12 Å for the α-helix and β-sheet conformations, respectively, with an accuracy of 0.01 Å. This result means that the (>N–)H · · · O(=C<) hydrogen bond strength (distance) of the β-sheet PLA must be stronger (shorter) than that of the α-helix one. The above N–H bond length difference between the α-helix and β-sheet forms seems to be related to the hydrogen bond strengths and amide proton chemical shifts. From the X-ray diffraction studies of PLAs by Arnott *et al.* [25,26], it is known that the distance between the nitrogen and oxygen atoms is 2.87 and 2.83 Å for the α-helix and β-sheet forms, respectively. This is consistent with the hydrogen bond distances between the nitrogen and oxygen atoms determined from X-ray diffraction and with the ^{1}H chemical shifts of amide proton signals found using the ^{1}H CRAMPS method.

Accordingly, it is reasonable to conclude that the amide proton of the β-sheet PLA is more strongly attracted to the oxygen than the proton of α-helical PLA.

Structural Studies of α-amino-acid Crystals by ^{1}H CRAMPS NMR

The ^{1}H CRAMPS NMR has become a very useful research tool,corresponding to X-ray crystallography [28,29]. This enabled to study crystal structure polymorphs of α-amino acids. Here, the author introduces

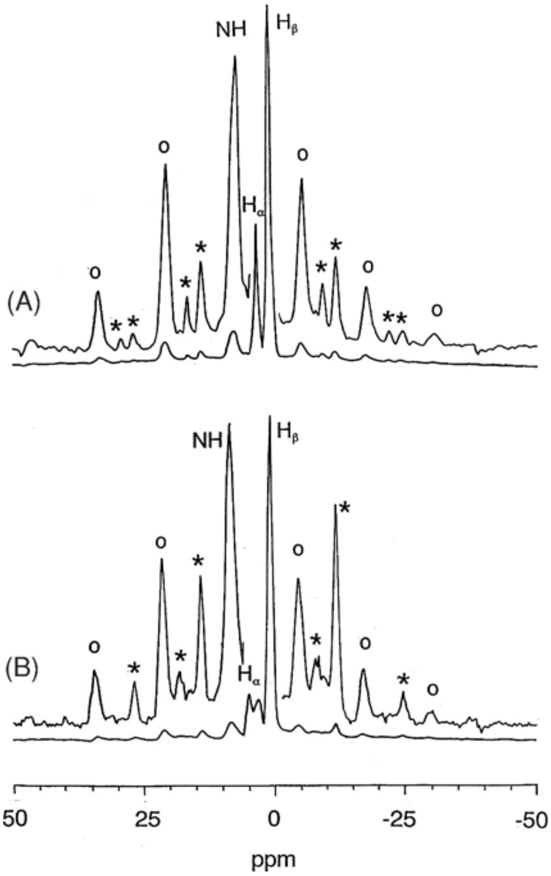

Fig. 9. NMR spectra (300 MHz ^{1}H CRAMPS) of fully ^{15}N-labeled poly(L-alanines) taking (A) α-helix and (B) β-sheet conformations in the solid state. Peak assignment: H^N, 10–8 ppm; H^α, 3.9–5.0; and H^β, 1.4–1.2 ppm. *Note*. –N–CH_2– peak (3.2–3.5 ppm) of *n*-butylamide group in spectrum (B). The sign (o) indicates the spinning sidebands (SSB) of H^N signal and the sign (*) indicates SSB of H^α and H^β signals.

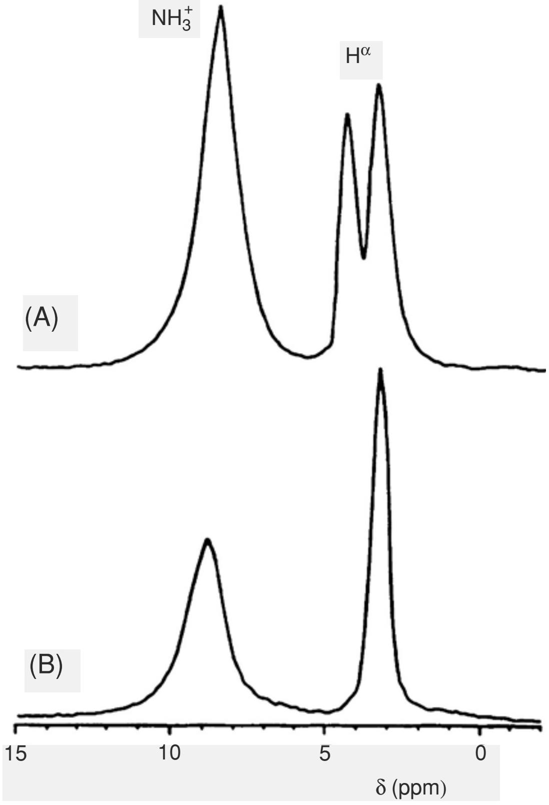

Fig. 10. NMR spectra (300 MHz ^{1}H CRAMPS) of glycine polymorphs: (A) α-glycine and (B) γ-glycine crystals.

the recent research example application to crystal structural analysis of glycine polymorphs [α-form (α-glycine) and γ-form (γ-glycine)] in order to test the power of ^{1}H CRAMPS NMR, compared with ^{13}C and ^{15}N NMR methods [3]. The γ-glycine [30,31] (hexagonal; P3_1 space group) is most stable at room temperature and converts to α-glycine [32,33] (monoclinic; P2_1/n space group) on heating to 165°C whereas β-glycine [30,31] (monoclinic; P2_1 space group) is very unstable.

Figure 10 shows the ^{1}H CRAMPS NMR spectra of (A) α-glycine and (B) γ-glycine crystals, together with each peak assignment. It is noteworthy that the H^α signal of α-glycine splits into two peaks (4.4 and 3.4 ppm) of equal height but that of γ-glycine gives a sharp singlet peak (3.3 ppm). The reason for this peak splitting may be attributable to a difference in the magnetic surroundings of two nonequivalent H^α protons in α-glycine, whereas they are equivalent and give a single peak in γ-glycine.

Thus, the ^{1}H CRAMPS NMR is very useful for the structural analysis of glycine crystals. It is hoped to accumulate more ^{1}H chemical shift data for other α-amino acid, oligopeptide, and polypeptide crystals in the future.

Polymer Dynamics

Dynamics of Amorphous Polymers

Fumitaka Horii
Institute for Chemical Research, Kyoto University, Kyoto 611-0011, Japan

Introduction

Individual structural units forming polymer molecules basically undergo their own local motions in different states although some of them may be cooperative motions. The modes and rates of the molecular motions are relatively well characterized in the crystalline state by solid-state NMR spectroscopy, but the analysis of the local motions in the noncrystalline state may not be straightforward because there are distributions in molecular motion associated with the noncrystalline structure. Several solid-state NMR analytical methods, which are summarized in Figure 3.1 in Ref. [1], have been already proposed and they are successfully applied to the characterization of different amorphous polymer materials. The outline of the characterization will be described in this contribution.

Spin Relaxation

The most basic analytical method is to measure spin relaxation parameters such as spin–lattice relaxation times (T_1) and spin–spin relaxation times (T_2) and to interpret them in terms of appropriate molecular motion models. However, the theory of the spin relaxation associated with the molecular motion is limited to a very simple case, the two-spin system having a constant internuclear distance [2–4]. As is well known, in the natural abundant ^{13}C–^{1}H two-spin system, ^{13}C T_1, T_2, and nuclear Overhauser effect (NOE) are expressed as [1–4]

$$\frac{1}{NT_1} = \frac{\gamma_H^2\gamma_C^2\hbar^2}{16r^6}\{J_0(\omega_H-\omega_C)+18J_1(\omega_C) + 9J_2(\omega_H+\omega_C)\},$$

$$\frac{1}{NT_2} = \frac{\gamma_H^2\gamma_C^2\hbar^2}{32r^6}\{4J_0(0)+J_0(\omega_H-\omega_C)+36J_1(\omega_H) + 18J_1(\omega_C)+9J_2(\omega_H+\omega_C)\},$$

$$\mathrm{NOE} = 1+\frac{9J_2(\omega_H+\omega_C)-J_0(\omega_H-\omega_C)}{J_0(\omega_H-\omega_C)+18J_1(\omega_C)+9J_2(\omega_H+\omega_C)} \times \frac{\gamma_H}{\gamma_C}. \tag{1}$$

Here, N is the number of protons chemically bonded to a given carbon and ω_H and ω_C are Larmor frequencies of ^{1}H and ^{13}C nuclei, respectively. $J_q(\omega)$ are the spectral densities that are the Fourier transforms for the autocorrelation functions $G_q(\tau)$ of the orientation functions that describe the random time fluctuation of the C–H internuclear vector having a correlation time τ_c:

$$J_q(\omega) = \int_{-\infty}^{+\infty} G_q(\tau)\exp(-i\omega\tau)\,\mathrm{d}\tau, \quad q = 0,1,2. \tag{2}$$

In the polymer systems even in the rubbery or dissolved state, the motion of the C–H vector cannot be described by a simple isotropic random fluctuation model with a single correlation time [1]. Although wide distributions of the correlation times are sometimes introduced, such treatments are not successful to interpret very high minimum values of T_1 for polymers that appear at a correlation time corresponding to $\sim\omega_c^{-1}$. Normally at least three independently superposed motions are necessary to describe the overall C–H motion of polymers and such models, frequently called as the 3τ model, successfully interpret the temperature dependency of T_1 including the T_1 minimum as well as the resonance frequency dependency of T_1 [1]. Recently some model-free treatments have also been proposed, considering plural superposed molecular motions with different correlation times. In the most generalized model-free treatment assuming the superposition of the overall isotropic motion and several anisotropic local motions, $G_q(\tau)$ are given by the product of the respective motions as follows: [1]

$$G_q(\tau) = G_I(\tau)\prod_{1}^{p-1} G_{Ai}(\tau),$$

$$G_I(\tau) = K_q\exp\left(\frac{-\tau}{\tau_I}\right) \qquad K_0 = \frac{4}{5}, K_1 = \frac{2}{15}, K_2 = \frac{8}{15}.$$

$$G_{Ai}(\tau) = S_i^2 + (1-S_i^2)\exp\left(\frac{-\tau}{\tau_{Ai}}\right) \qquad i = 1, 2, \ldots, p-1. \tag{3}$$

Here, τ_{Ai} and S_i^2 are the correlation time and the order parameter for the ith inner motion, respectively. When

Graham A. Webb (ed.), Modern Magnetic Resonance, 607–613.
© 2008 *Springer.*

$p = 3$ and $\tau_{A1} \ll \tau_{A2} \ll \tau_I$, the total correlation function reduces to

$$G_q(\tau) = K_q\left[S_2^2 S_1^2 \exp\left(\frac{-\tau}{\tau_I}\right) + (1 - S_2^2)S_1^2 \exp\left(\frac{-\tau}{\tau_{A2}}\right) + (1 - S_1^2)\exp\left(\frac{-\tau}{\tau_{A1}}\right)\right]. \tag{4}$$

This equation, which corresponds to the equation derived for the 3τ model, was successfully used to interpret the temperature and frequency dependencies of ^{13}C T_1 and NOE for the CH_2 carbons in the *rrr* units of poly(methyl methacrylate) in $CDCl_3$ solution [1]. Through such an analysis, the correlation times, activation energies, and order parameters of the respective motions can be obtained without the construction of the detailed models for the respective motions.

One-Dimensional MAS Spectra

When one-dimensional (1D) MAS spectra of certain solid polymer samples are measured at different temperatures under ^{1}H high-power decoupling, some resonance line is sometimes observed to greatly change in linewidth with the change in temperature, for example, as seen for the C6 and C7/8 resonance lines of solid poly(2-hydroxypropyl ether of bisphenol-A) (phenoxy resin) shown in Figure 1 [5]. This process frequently also accompanies the decrease in resonance intensity when the spectra are measured by the CP method. Such changes of the resonance lines are ascribed to the onset of the molecular motion having a rate corresponding to the ^{1}H dipolar decoupling amplitude or the ^{13}C radio frequency amplitude. The former change in linewidth is expressed as [6–8]

$$\Delta\nu = \Delta\nu_0 + \Delta\nu_1\left\{1 + \frac{2}{\pi}\arctan\left[\alpha(T_0 - T)\right]\right\} + \frac{\lambda M_2}{\pi}\frac{\tau_c}{\left(1 + \tau_c^2\omega_1^2\right)} \tag{5}$$

when the chemical shift anisotropy (CSA) of the ^{13}C nucleus in question is negligibly small. Here, $\Delta\nu_0$ is the intrinsic linewidth produced by inhomogeneous experimental factors, $\Delta\nu_1$ the linewidth at a temperature T_0 below T_g generated by the distribution of isotropic chemical shifts due to inhomogeneous local structural factors for glassy polymers, α and λ adjustable parameters, M_2 the second moment of the ^{13}C–^{1}H dipolar interaction, τ_c the correlation time of the molecular motion, and ω_1 the ^{1}H decoupling amplitude in Hz. The C7/8 line was found to be successfully analyzed in terms of Equation(5) by assuming the William–Landel–Ferry type temperature dependency of the correlation time and thus the correlation times were determined as a function of temperature. In contrast, the correlation times for the C6 line were obtained at different temperatures by considering the large CSA of this ^{13}C nucleus [5].

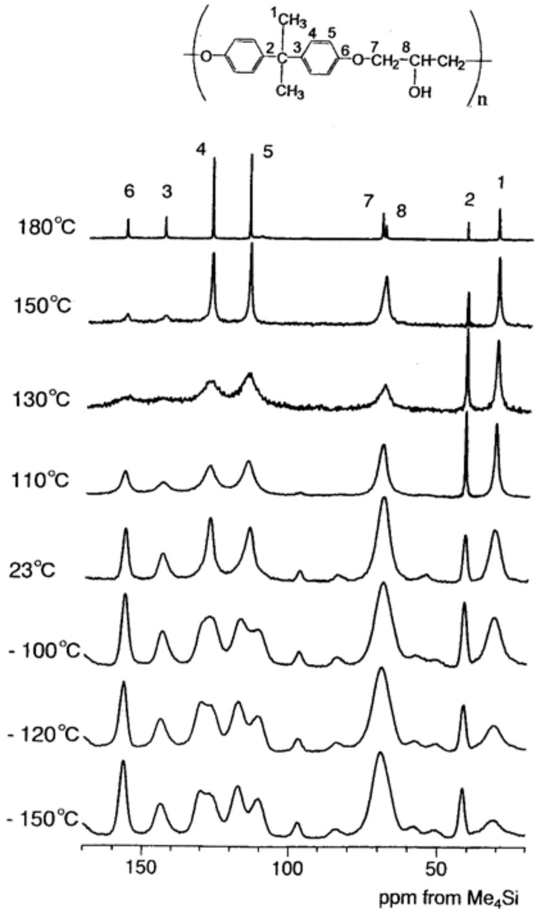

Fig. 1. CP/MAS ^{13}C NMR spectra of phenoxy resin at different temperatures. (Reproduced from Ref. [5].)

In Figure 1, another type of spectral change is observed for the C4 and C5 line. These lines split into two constituent lines at lower temperatures and such two lines merge into a single line at a certain temperature. Similar spectral changes are frequently observed and these processes are analyzed by the two-site exchange model that is expressed as [2]

$$I(\omega) = \frac{1}{2}\frac{\kappa(\omega_1 - \omega_2)^2}{(\omega - \omega_1)^2(\omega - \omega_2)^2 + \kappa^2[2\omega - (\omega_1 + \omega_2)]^2}. \tag{6}$$

Here, ω_1 and ω_2 are the resonance frequencies for the two sites and κ is the exchange rate. By using this model, the rates of the phenylene flip motion were determined at different temperatures for the polymer shown in Figure 1 [5]. Characteristic chain conformations of the spacer CH_2 sequences of liquid crystalline polymers were also clarified by using Equation (6) [9–11].

Lineshape Analyses

More general characterization methods of molecular motion of solid polymers are lineshape analyses of ^{2}H, ^{13}C CSA, and ^{13}C–^{1}H dipolar spectra in terms of appropriate molecular motion models. Here, ^{2}H and ^{13}C CSA analyses are briefly described for some amorphous polymers.

In the case of ^{2}H NMR, the resonance frequency ω_r is given by [12]

$$\omega_r = \omega_0 \pm \Delta_0(3\cos^2\zeta - 1 - \eta_Q \sin^2\zeta \cos 2\xi). \quad (7)$$

Here, ω_0 is the resonance center and the second term is the resonance shift due to the quadrupolar interaction. Δ_0 the constant inherent to the nucleus, ξ and ζ the polar angles to describe the direction of the static magnetic field B_0 in the principal axis frame of the field gradient tensor, and η_Q the anisotropic parameter. Since ξ and ζ are widely distributed in powdered samples in the rigid state, an observed ^{2}H spectrum has a characteristic lineshape called Pake pattern as a result of the reflection of the distributions. When molecular motion of some structural unit including the ^{2}H nucleus occurs, ξ and ζ will undergo time changes depending on the mode and rate of the molecular motion. In this case, the principal axis frame $x_P y_P z_P$ of the field gradient tensor, which is defined for a particular chemical bond associated with the ^{2}H nucleus, should be successively correlated to the molecular frame $x_M y_M z_M$, the reference frame $x_R y_R z_R$, and the laboratory frame xyz, by considering the mode of molecular motion. Figure 2 shows the case of the phenylene flip motion with a flip angle of δ, where the *ortho* hydrogen atom is deuterated [1]. By the successive coordination transformations using the corresponding transformation matrices $\boldsymbol{R}(\alpha, \beta, \gamma)$, the resonance frequency ω_r is finally expressed as a function of δ for the phenylene ring whose bond axis is described by the polar angles $-\phi$ and $-\theta$ in the laboratory frame.

When the phenylene ring undergoes the flip motion with a rate of κ in s^{-1} between the sites described by $\delta = 0$ and $\delta = \delta$, the resonance line $I(\omega)$ will be expressed by using the two-site exchange model given by Equation (6). Since ϕ and θ are distributed statistically at random in powdered samples, the real resonance line $I_{pw}(\omega)$ should be integrated with regard to all possible ϕ and θ values [1].

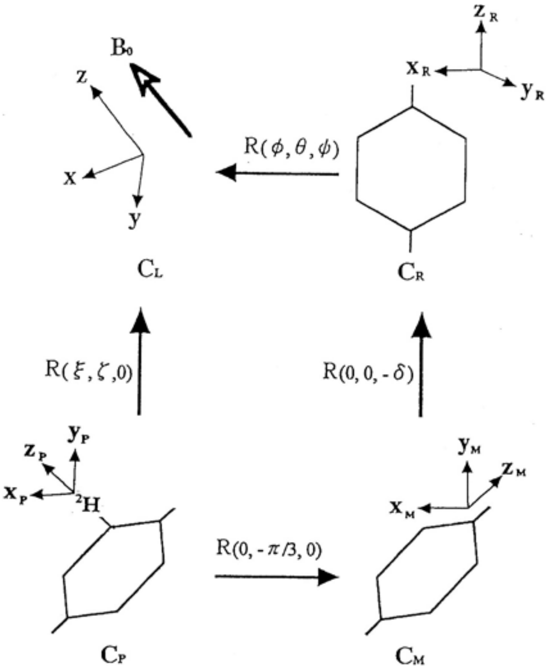

Fig. 2. Schematic representation of the coordinate transformation from the principal axis frame (C_P) through the molecular frame (C_M) and the reference frame (C_R) to the laboratory frame (C_L). (Reproduced from Ref. [1])

Figure 3 shows observed and simulated ^{2}H NMR spectra at different temperatures for glassy phenylene-deuterated poly(ethylene terephthalate) (PET) [13]. The phenylene motion is almost hindered below 0 °C because the spectra obtained are in good accord with the rigid Pake pattern. Figures 3b shows ^{2}H NMR spectra simulated by assuming the log-Gaussian distribution in the 180° flip rate as shown in Figure 3c. Although a good fit is obtained at each case, the rate distributions are unexpectedly very broad at higher temperatures. This may be due to the neglect of the distribution in flip angle. Figure 3D shows simulated ^{2}H NMR spectra obtained by assuming the distributions in flip rate and flip angle as shown in Figure 3e and f, respectively. Good fits are also obtained at the respective temperatures and the distribution in flip rate seems to be appropriately narrow even at higher temperatures. The activation energy 63.6 kJ/mol estimated from the Arrhenius plot of the average flip rate is in good agreement with the value obtained by dynamic mechanical measurements [14] in this case. Similar distributions in flip angle were also evaluated for the phenylene motion of bisphenol-A polycarbonate (BPAPC) by 2D ^{2}H exchange NMR spectroscopy [15].

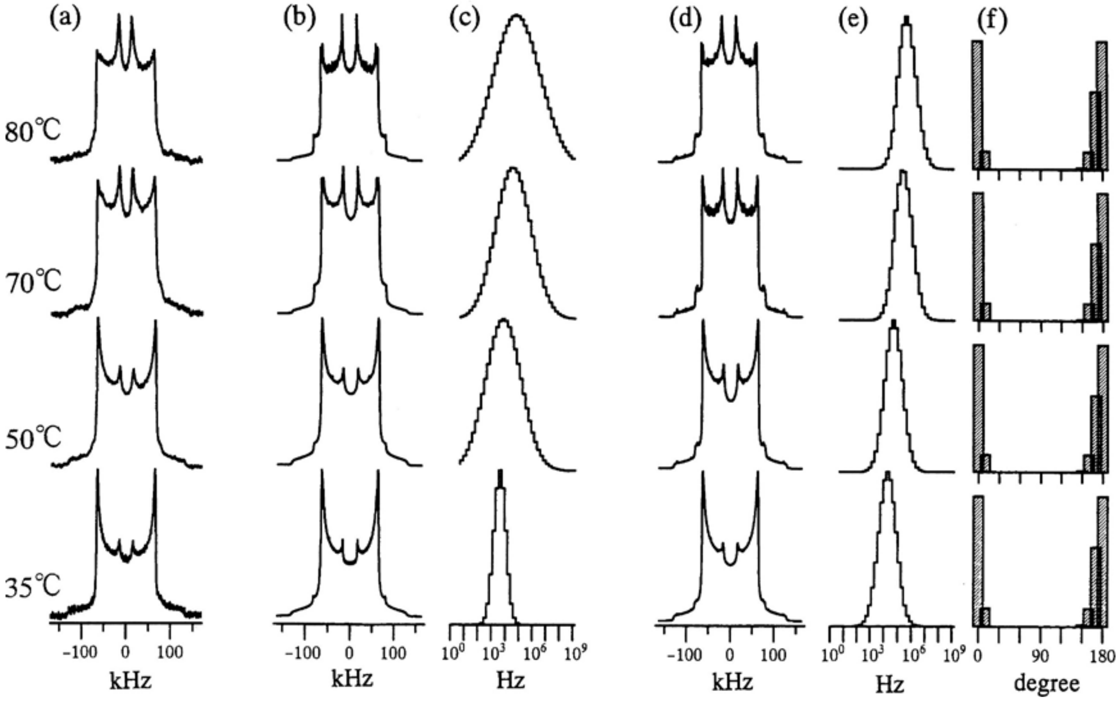

Fig. 3. Observed and simulated ^{2}H NMR spectra of the phenylene deuterated PET at different temperatures: (a) observed spectra, (b) simulated spectra obtained by introducing the distributions in flip rate as shown in (c), (d) simulated spectra obtained by introducing both distributions in flip rate and flip angle as shown in (e) and (f), respectively. (Reproduced from Ref. [13].)

In natural abundant ^{13}C NMR, the resonance frequency ω_r is given by [16,17]

$$\omega_r = \omega_0 \frac{\mathrm{Tr}\left(\sigma_{ij}\right)}{3} + \frac{2}{\sqrt{6}} \omega_0 A_{20}^L,$$

$$A_{20}^L = \frac{\left[3\sigma_{33}^L - \mathrm{Tr}\left(\sigma_{ij}^L\right)\right]}{\sqrt{6}}. \tag{8}$$

Here, σ_{ij} and σ_{ij}^L are the *ij* components of the chemical shift tensors σ and $\sigma^{\ L}$ in the principal axis and laboratory frames, respectively. A_{20}^L is the 20th component for the irreducible tensor A^L in the laboratory frame which describes the chemical shift term of the Hamiltonian of the system together with another irreducible tensor T^L. Since A_{20}^L should be described by the corresponding A_{20} in the principal axis frame, some coordinate transformations are performed from the principal axis frame to the laboratory frame through the molecular frame and the reference frame depending on the mode of molecular motion similarly to the case shown in Figure 2. In real solid-state ^{13}C NMR experiments, CSA spectra are measured at different temperatures by using one of the methods hitherto proposed [1]. Figure 4 shows CSA spectra of the CH carbon of glassy BPAPC measured at different temperatures by the selective excitation switching angle sample spinning (SASS) [18]. These spectra are well reproduced under the fast limit condition ($\kappa \geq 10^5$ Hz) by the introduction of wide distributions in flip angle around 0° and 180° for the phenylene motion. The appreciable discordance between the simulated and observed spectra at higher temperatures may be due to the onset of the hindered fluctuation of the flip axis.

The isotropization process of the ^{13}C CSA above T_g was also successfully analyzed for the carbonyl carbon ^{13}C-enriched poly(ethyl methacrylate) [19]. Here, the multisite analysis was conducted by using the exchange matrix Π that contains the probability per unit time for an exchange between site *i* and site *j* as matrix elements $(\Pi)_{ij}$ [19,20]. However, fully good fits between the observed and simulated CSA spectra were obtained for both a random jump model and a rotational diffusion model having single correlation times. The reliable discrimination of the two models should be made by 2D ^{13}C CSA exchange NMR spectroscopy described below.

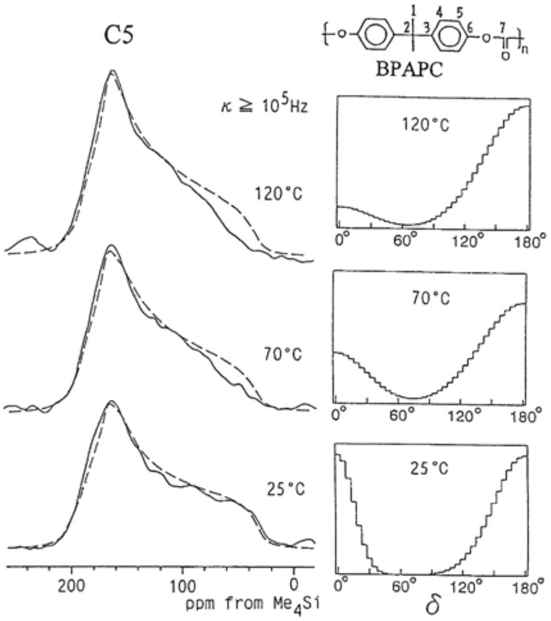

Fig. 4. ^{13}C CSA spectra for the C5 carbon of BPAPC at different temperatures measured by selective excitation SASS. Solid line: observed, broken line: simulated. The histograms indicate the distributions of the flip angle δ for the phenylene group. (Reproduced from Ref. [18].)

2D Exchange Spectra

2D exchange NMR spectroscopy is one of the most frequently used 2D NMR methods in the field of solid-state NMR. In Figure 5, for example, a 2D CP/MAS ^{13}C exchange NMR spectrum is shown for the resonance lines of the C4 and C5 phenylene carbons measured at –120 °C for poly(2-hydroxypropyl ether of bisphenol-A) whose chemical structure is depicted in Figure 2 [5]. At a mixing time of 2.0 s, exchange peaks are evidently observed for the C4 and C5 carbons themselves without any corresponding peak between the C4 and C5 carbons. This fact indicates the occurrence of the phenylene 180°-flip motion having a rate of the order of 1 s^{-1}. The correlation times τ_c of the flip motion are also determined at each temperature by analyzing the exchange peak intensity $I(t_m)$ as a function of mixing time t_m using the following equation: [21]

$$I(t_m) = \frac{n-1}{n}\left[1 - \exp\left(-\frac{t_m}{\tau_c}\right)^{\beta}\right], \tag{9}$$

where n is the number of the sites and β is the Kohlrausch–Williams–Watts (KWW) parameter [22].

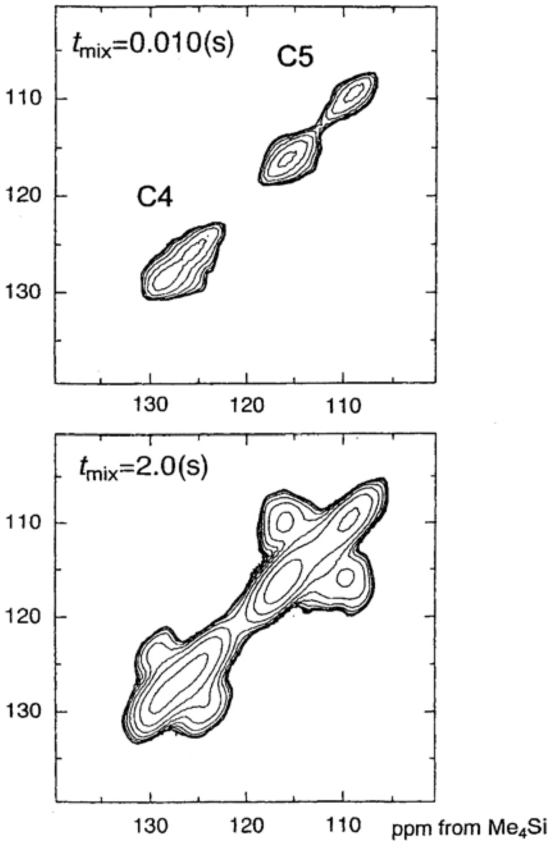

Fig. 5. 2D CP/MAS ^{13}C exchange spectra for glassy phenoxy resin at −120 °C. (Reproduced from Ref. [5].)

The molecular motion of main chains of amorphous polymers can be also characterized in the glass–rubber transition region by 2D ^{13}C exchange NMR spectroscopy. In this case, an observed ^{13}C CSA exchange spectrum is analyzed in terms of various molecular motion models: The time domain signal $G(t_1,t_2,t_m)$ is expressed as [20]

$$G(t_1, t_2, t_m) = <\mathbf{1}|\exp[(\Pi + i\omega)t_2]\exp[(\Pi)t_m] \times \exp[(\Pi)t_1]\boldsymbol{P}_0|\mathbf{1}> \tag{10}$$

Here, Π is the exchange matrix described above, ω is the time-evolution matrix with $(\omega)_{jk} = \delta_{jk}\omega_{jk}$ that describes the resonance frequencies at the respective sites, and $\boldsymbol{P}_0$ is the matrix for the initial site distribution. The unit matrices <**1**| and |**1**> are used for a simple expression of the equation. After the 2D Fourier transform of $G(t_1,t_2,t_m)$, the simulated 2D exchange spectra are compared with the corresponding observed spectra.

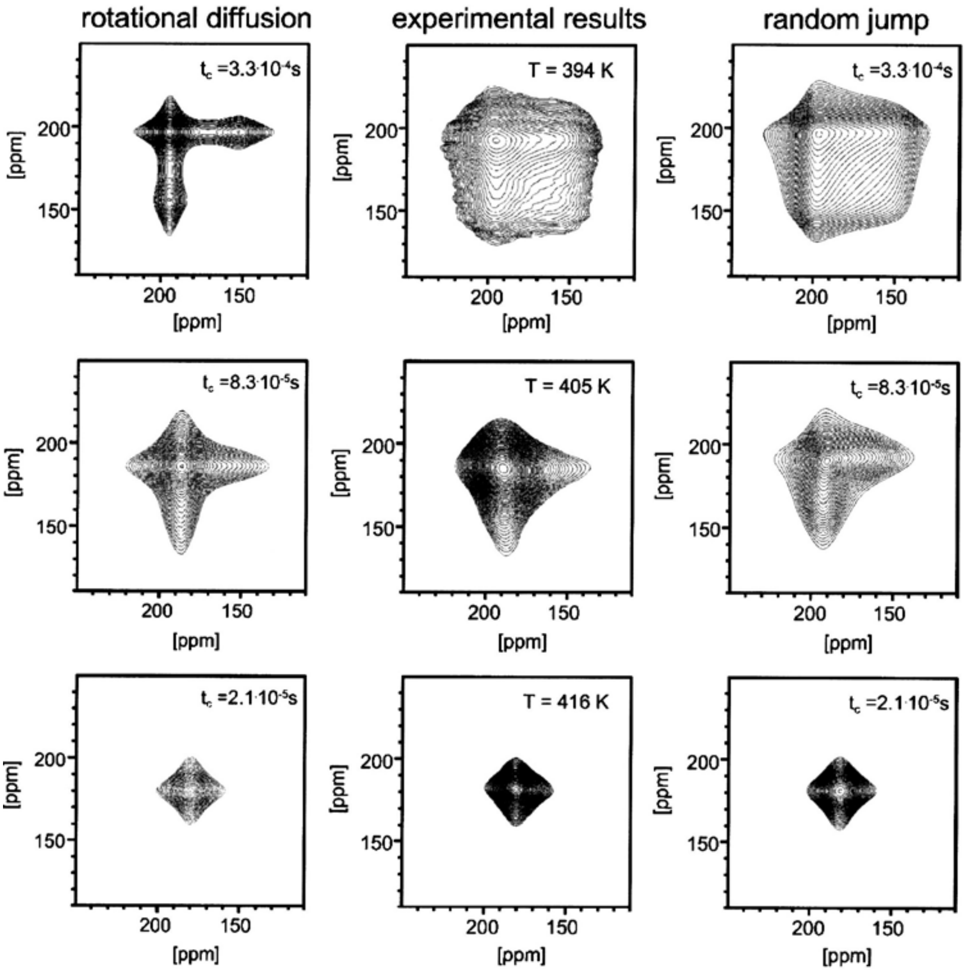

Fig. 6. Observed and simulated 2D ^{13}C CSA exchange spectra for carbonyl carbon ^{13}C-enriched poly(ethyl methacylrate) at different temperatures above T_g. Single correlation times denoted by t_c were used for both models. (Reproduced from Ref. [19].)

Figure 6 shows observed and simulated 2D ^{13}C CSA exchange spectra obtained at different temperatures above T_g for carbonyl carbon ^{13}C-enriched poly(ethyl methacrylate) [19]. It is clearly found that the random jump model is a much more suitable model than the rotational diffusion in this case, although these two models cannot be discriminated in the 1D ^{13}C CSA lineshape analysis as described above. Moreover, it should be noted that single correlation times depicted by t_c in Figure 6 are reasonably used at each temperature instead of the introduction of any distribution. Echo decay analyses combined with 2D exchange NMR spectroscopy also confirmed that such motionally averaged process is adequately described in terms of the random jump model with a single correlation time [19].

Molecular Motions of Crystalline Polymers by Solid-State MAS NMR

Toshikazu Miyoshi
Nanotechnology Research Institute, National Institute of Advanced Industrial Science and Technology (AIST),
Higashi 1-1-1 Tsukuba, Ibaraki, 305-8565, Japan

Overview

Chain dynamics in the crystalline region of semi-crystalline polymers play an important role for bulk material properties such as mechanical strength, creep, drawability, crystallization process, and crystal transformation. Therefore, it is important to characterize chain dynamics in detail. 2D exchange NMR is a reliable tool for polymer dynamics analysis, because this method provides motional geometry and time-kinetic parameters quantitively. However, it is difficult to apply this sophisticated method for polymers with chemically complicated polymers in natural abundance. 1D-MAS exchange NMR method is possible to give the same information, and has a great advantage of characterizing molecular dynamics for multi-functional groups of molecules without isotope labeling. In this contribution, we briefly explain 1D-MAS exchange NMR, and their applications to slow dynamics of crystalline polymers with chemically complicated structures in natural abundance. We will show which part of polymer in the crystalline region contributes to mechanical property and what type of motions occur in the unstable crystalline form prior to crystal–crystal transformation.

1D-MAS Exchange NMR

There are several 1D-MAS exchange NMR methods [1–6] which enable us to measure detailed dynamic information of target molecules without isotope labeling. Among them, CODEX method [5,6] is most useful for polymers with chemically complicated structures and small CSA [7–9]. The CODEX NMR consists of an exchange and reference parts, and utilizes the recoupling of the CSA interaction by 180° pulses trains in the two evolution periods sandwiching a mixing period (t_{mix}). The effect is signal decay due to the dephasing of magnetization brought about by changes in orientation-dependent CSA due to a re-orientational dynamic process during t_{mix}. The resulting dephasing leads to a decay of the signal-intensity in the exchange spectrum (S). Further, the relaxation such as T_1 and T_2 during t_{mix} and evolution time (Nt_{r}), respectively, and pulse length errors also lead to signal decay. To remove these effects, a reference spectrum is acquired. The motional correlation time and information about the motional geometry can be obtained by plotting the ratio (S/S_0) vs. $t_{\mathrm{mix},}$ and (S/S_0) vs. Nt_{r}, respectively [5–11].

In typical organic compounds in natural abundance, the time constant of spin diffusion (τ_{sd}) is on the order of ∼ s under MAS condition [12]. Therefore, spin exchange due to spin diffusion also contributes to the exchange decay with increasing t_{mix} up to several seconds. The dynamic process is thermally activated, and thus, the obtained correlation time depends on temperature. On the other hand, spin diffusion is in a good approximation temperature independent in the regime of interest. Therefore, the spin-diffusion effect is obtained from the exchange decay at low temperature where molecular dynamics does not contribute to the exchange decay. Then, pure exchange decay due to dynamic process is obtained [7–10,12]. In the case of semi-crystalline polymers, ^{13}C NMR signals in the amorphous regions overlaps with the crystalline signals. Therefore, relaxation filter such as T_1 and $T_{1\rho}$, which suppresses amorphous contributions to S and S_0 is also incorporated into the 1D-MAS exchange pulse program [7–9]. Then, pure crystalline dynamics for semi-crystalline polymers is investigated by 1D-MAS exchange NMR.

Mechanical Property vs. Chain Dynamics

Isotactic-poly(4-methyl-1-pentene) is commercially available and one of the industrially important polymers [13]. The crystalline region of *i*P4M1P shows a lower density than the amorphous region at room temperature. Figure 1a and b show ^{13}C CPMAS NMR spectra and CSA spectra, respectively, for *i*P4M1P crystallites (form I). The polymer structure for *i*P4M1P crystallites [14] and signal assignments are also inserted in Figure 1a. ^{13}C high-resolution signals for all functional groups appear in the narrow chemical shift range of 22–46 ppm. The CSA spectra for the main-chain signals overlap with those for the side-chain ones as shown in Figure 1b. Therefore,

Graham A. Webb (ed.), Modern Magnetic Resonance, 615–619.

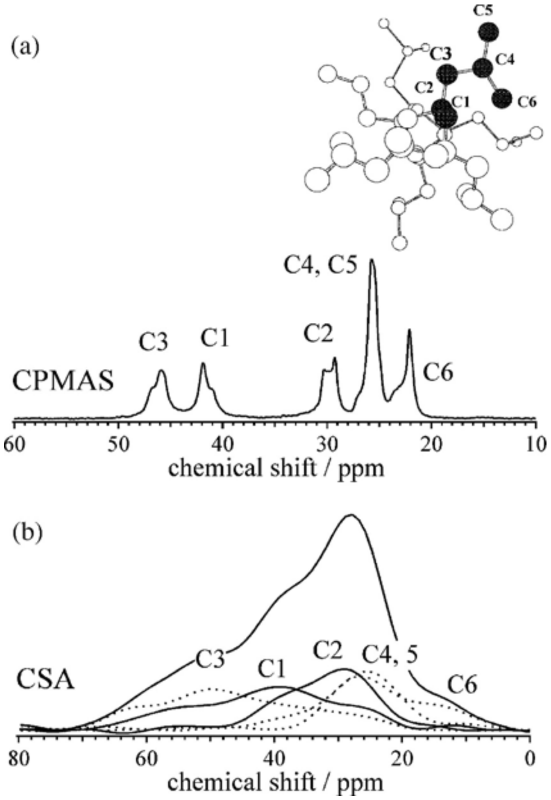

Fig. 1. (a)^{13}C CPMAS NMR spectra of *i*P4M1P crystallites at room temperature [7,8]. The 7_2 helical structure for form I crystallites of *i*P4M1P determined by WAXD [14], and NMR signal assignment is shown as an insert. (b) ^{13}C CSA spectra for *i*P4M1P crystallites and their summation (solid curve) at room temperature. ^{13}C CSA spectra were obtained by 2D SUPER experiments [15]. The solid and broken curves show main- and side-chain spectra.

it is difficult to apply 2D exchange NMR to detailed dynamics analysis of *i*P4M1P crystallites. Figure 2a shows CODEX exchange and reference NMR spectra, respectively, with Nt_r of 2.2 ms and $t_{\text{mix}} = 107$ ms at 360 K [8]. The signal intensities for the side-chain signals C3 and C6 as well as the main-chain signals C1 and C2 in the exchange spectrum (S) are much smaller as compared to those in the reference spectrum (S_0). These CODEX spectra show that overall motions occur in the crystalline regions. The Nt_r dependence of (S/S_0) relies on CSA size, tensor orientation, and motional geometry [6]. Figure 2b shows the simulated CODEX curves for C1 with jump angles of 10, 20, 30, 50, 70, and 103° around its chain axis. The simulations show steep decays in the initial period with increasing jump angle. The Nt_r dependence of (S/S_0) for the C1 signal at $t_{\text{mix}} = 107$ ms and 333 K is shown in Figure 2c. The helical jump angle between the neighboring sites is $360^\circ \times 2/7 = 103^\circ$. Actually, *i*P4M1P crystallites show slightly disordered 7_2 helical conformations in the lattice. Therefore, jump angles between the seven neighboring sites deviate from 103°, and are 122, 84, 93, 145, 96, 72, and 109° [8,14]. The CODEX dephasing curve for each jump angle was calculated. The average one and the experimental data for (S/S_0) intensity for C1 signal are shown in Figure 2c. The experimental data are well consistent with the simulated and averaged curve. This result shows that helical jump motions happen in *i*P4M1P crystallites as well as in PE [16], *i*PP [17,18], POM [18,19], PEO [20], and form III of *i*PB crystallites [21].

Figure 3a and b show t_{mix} dependencies of $(S/S_0)^*$ for the main-chain signals C1 (○) and C2 (●) and the side-chain signals C3 (□) and C6 (×), respectively, in *i*P4M1P crystallites at 360 K, where $(S/S_0)^*$ shows pure exchange curve after spin-diffusion correction [8]. t_{mix} dependences of $(S/S_0)^*$ for C3 and C6 in the side-chain almost match those for the main-chain signals C1 and C2 within the experimental errors. The plateau values for the main-chain signals are in agreement with those of the side-chain, too. These evidences indicate that the side chain moves in concert with the main chain in the crystallites, and there are no slow independent motions. The solid curves in Figure 3a and b provide kinetic parameters such as available site number, correlation time, and distribution width of correlation time [6,8]. The correlation times for helical jump motions obtained through the C2 signal (●) are plotted in Figure 3c. The mechanical relaxations reported by different authors [22,23] are also inserted in Figure 3c. The correlation times for helical jump motions are reasonably agreement with the mechanical relaxations. These relaxations were believed to the segmental motions in the amorphous region. The obtained CODEX NMR results concluded that overall motions in the crystalline region also contribute to the mechanical relaxation.

Crystal Transformation vs. Molecular Dynamics

Solid-state crystal–crystal transformations frequently occur in crystalline polymers, spontaneously [24] or under specific treatments, for example, mechanical stretching [25]. Crystal–crystal transformations accompany changes in the molecular structure such as conformation, packing, or both. These structural changes require internal rotations around chemical bonds, lateral displacements, translations and rotations of the polymer chains in the restricted space. In most of the crystal–crystal transformations, the chirality of the helix is preserved due to the spatial restrictions imposed by the lattice [24]. These structural changes are commonly discussed on the basis of static

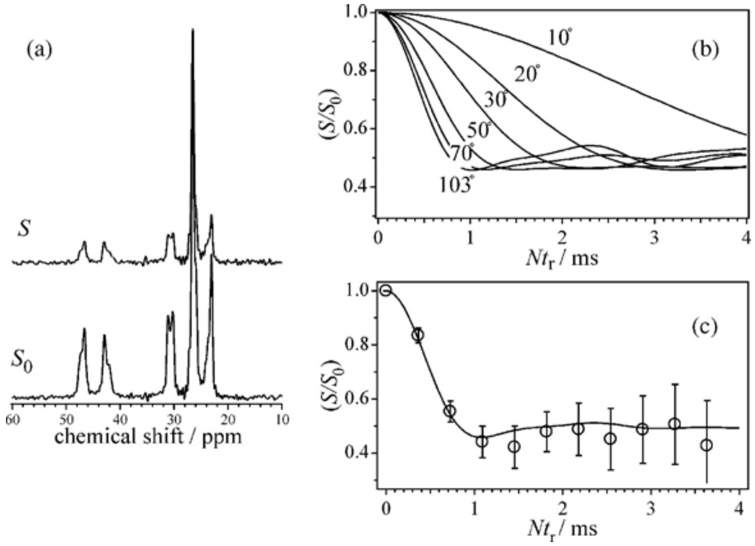

Fig. 2. (a) ^{13}C CODEX exchange and reference NMR spectra of *i*P4M1P crystallites, with $t_{\mathrm{mix}} = 107$ ms and $Nt_{\mathrm{r}} = 2.2$ ms under MAS frequency of 3000 ± 3 Hz, measured at 360 K [8]. (b) ^{13}C CODEX Nt_{r} simulated curves for the C1 signal assuming different jump angles around the chain axis in a uniform 7_2 helix. (c) ^{13}C CODEX Nt_{r} dependence of (S/S_0) for the C1 signal (○) and the solid curve is the average of the simulated curves for jump angles with 122, 84, 95, 145, 96, 72, and 109° in the disordered 7_2 helix.

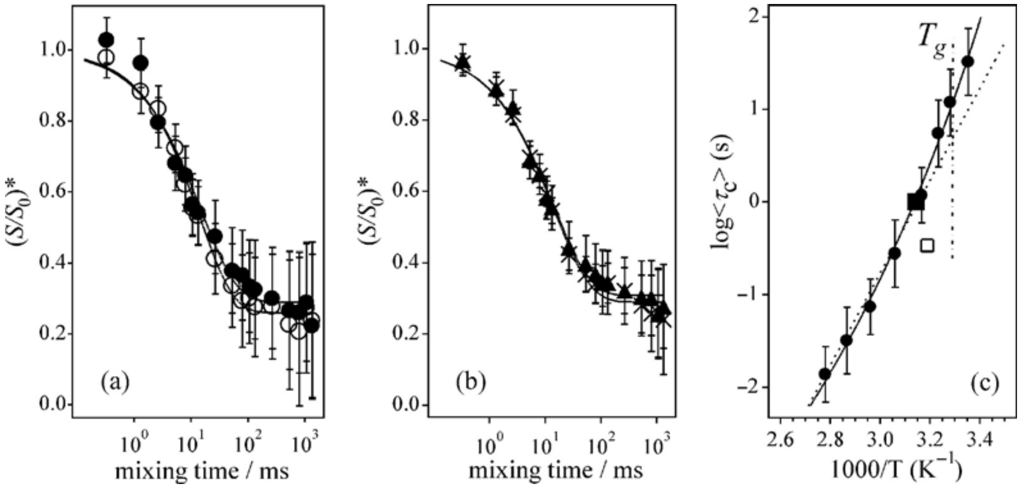

Fig. 3. ^{13}C CODEX exchange curves of $(S/S_0)^*$ intensities for the main chain [C1 (○) and C2 (●)] (a) and the side-chain [C3 (□) and C6 (×)] (b) for *i*P4M1P crystallites at 360 K [8]. The solid curves show the best fits to the experimental data using $(S/S_0)^* = 1\text{-}p(1\text{-}\exp(-t_{\mathrm{mix}}/\tau_{\mathrm{c}})^{\beta})$. p is determined by the number of sites m accessible by the dynamic process, $p = (m-1)/m$, τ_{c} is the correlation time, and β represents the distribution of correlation time. The fitting of $(S/S_0)^*$ of C2 yields $p = 0.70 \pm 0.12$, $\tau_c = (13.9 \pm 1.3)$ ms, $\beta = 0.71 \pm 0.11$, which are well consistent with the other signals (C1: $p = 0.74 \pm 0.02$, $\tau_c = (14.1 \pm 1.1)$ ms, $\beta = 0.72 \pm 0.05$, C3: $p = 0.69 \pm 0.03$, $\tau_c = (14.3 \pm 1.3)$ ms, $\beta = 0.65 \pm 0.05$, and C6: $p = 0.71 \pm 0.03$, $\tau_c = (14.3 \pm 1.3)$ ms, $\beta = 0.66 \pm 0.05$) within experimental errors. (C) Arrhenius diagram of the correlation times for helical jumps (●) of *i*P4M1P crystallites obtained by CODEX. The error bars mean a distribution width for the correlation times, assuming a log-Gaussian distribution. The mechanical data of *i*P4M1P by Reddy *et al.* [22] and Datch [23] are also shown as (■) and (□), respectively. The broken line shows best fitted one with an activation energy of 95.2 ± 5.3 kJ/mol. The solid curve shows WLF one with best fitted parameters of C1 = 8.4 ± 1.2, C2 = 75 ±17 K, and $T_{\mathrm{s}} = 294 \pm 3$ K. The short and dashed line shows T_{g} of *i*P4M1P, which was determined by DSC.

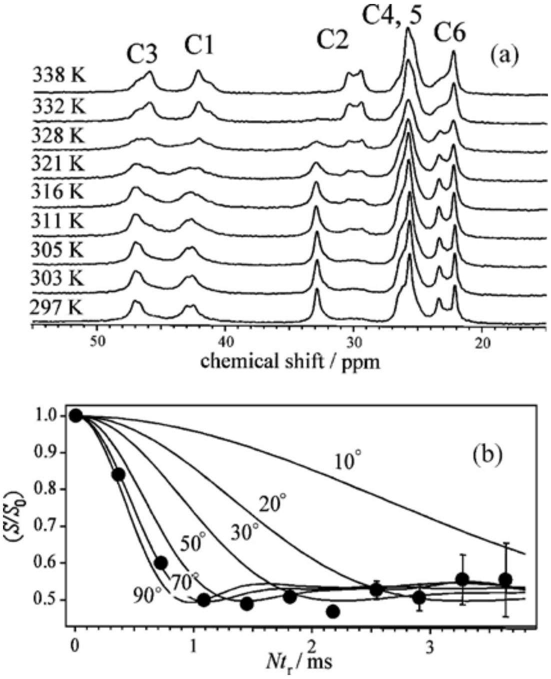

Fig. 4. (a) ^{13}C CPMAS NMR spectra of form III-rich of *i*P4M1P at various temperatures. ^{13}C CPMAS NMR spectra show unstable form III transforms into stable form I above 311 K [9]. The signals assignments are also inserted. (b) ^{13}C CODEX Nt_r dependence of C1 (●) for form III crystallites of *i*P4M1P with a mixing time of 107 ms under MAS frequency of 5500 ± 3 Hz at 311 K. The error bars were obtained from signal–noise ratios of exchange and reference spectra. The solid curves show simulated CODEX Nt_r attenuations for C1 signal with jump angles of 10, 20, 30, 50, 70, and 90° around the chain axis of a uniform 4_1 helix.

crystalline structures before and after the transformations, however, it is often expected that molecular dynamics plays an important role for the crystal–crystal transformation. Solid-state NMR directly can probe what type of motions occur in an unstable form prior to crystal–crystal transformation.

*i*P4M1P shows complicated polymorph of forms I–V, depending on the crystallization condition such as pressure, solvent, and thermal history [13]. Here, we address crystal–crystal transformation from form III (4_1 helix) into form I (7_2 helix) [9]. Figure 4a shows ^{13}C CPMAS NMR spectra for the form III-rich for *i*P4M1P as a function of temperature. The signal assignments are also demonstrated in Figure 4a. Above 311 K, the transformation from form III into form I is observed through the C2 signal. Since the C2 signal has significantly different chemical shifts in the different forms I and III, the line shape and chemical shift of the C2 signal are good indicators of the structural and dynamics changes due to the transformation. Below 338 K, the chemical shift of the C2 signal for form III is almost invariant. On the other hand, the line width shows motional broadening, indicating that segmental motions occur in form III crystallites prior to transformation.

Figure 4b shows CODEX Nt_r dependence of the C1 signal for form III and the solid curves showing CODEX recoupling curves for different hypothetical jump angles around its helical axis [9]. The experimental result of C1 signal shows a steeper decay during the initial evolution period and is well consistent with simulated jump angles of 70–90°. This NMR result directly detects the large amplitude overall motions in unstable crystalline form prior to the transformations. Similarly, poly(tetrafluoroethylene) (PTFE) [26] and form III of *isotactic*-poly(1-butene) (*i*PB) [21] also shows rotational motions with large amplitude before the transformations.

Concluding Remarks

In this contribution, we showed that slow molecular dynamics in the correlation times of 10^{-2} ~10^{2} s can be investigated in terms of 1D-MAS exchange NMR method in natural abundance. Fast and intermediate dynamics can also be investigated by other methods under MAS in natural abundance[15,27,28]. These methods should also be useful in understanding the crystallization process of semi-crystalline polymers.

Dynamics in Polypeptides by Solid State ^{2}H NMR

Toshifumi Hiraoki
Department of Applied Physics, Graduate School of Engineering, Hokkaido University, N13W8, Kita-ku, Sapporo 060-8628, Japan

Introduction

Solid state ^{2}H NMR parameters are almost exclusively governed by the quadrupole interaction with electric field gradient (EFG) tensor at the deuteron site [1–3]. The EFG is entirely intramolecular in nature. Thus molecular order and mobility are monitored through the orientation of individual C–^{2}H bond direction. Therefore, ^{2}H NMR is a powerful technique of studying local molecular motions. It enables us to discriminate different types of motions and its correlation times over the wide frequency range. The side chain of a polypeptide have remarkable multiple motional freedom about multiple bonds, while the main chain forms the regular secondary conformation such as α-helix and β-sheet which are presumed to be a rigid structure. In this section, we focus on the dynamics of both side- and main-chains of synthetic polypeptides deuterated at several positions by solid state ^{2}H NMR.

Methyl Group

Figure 1(a) shows the temperature dependence of ^{2}H NMR spectra of the left-handed ω helical poly(β-[$^2H_3$]methyl L-aspartate)(PMLA-d$_3$) [4]. The spectrum at $-125\,^\circ$C is an axially symmetric powder pattern with the quadrupole splitting $\Delta\nu_q$ of 38 kHz, showing a fast reorientation of the methyl group. There is no substantial change in line shapes from -125 to 50 °C. Remarkable change is observed at higher temperatures above 50 °C. The signal-to-noise ratio of a spectrum becomes worse and the integrated intensity of a spectrum decreases. These results suggest the presence of motions of the rate between 10^4 and 10^6/s. $\Delta\nu_q$ decreases from 38 to 34 kHz on going from -125 to 119 °C. These values are slightly smaller than the theoretically predicted value of 41.7 kHz in the case of extremely fast reorientation about C$_3$ axis, suggesting the presence of additional rapid librations of the C$_3$ axis. This small decrease in $\Delta\nu_q$ may be accounted for librations of the C$_3$ axis within a cone of semi-angle of 20°–30°.

Inspection of the inversion-recovery ^{2}H NMR spectra reveals that the parallel components of a spectrum has a shorter T_1 than the perpendicular components in the temperature range from -125 to 20 °C. Such T_1 anisotropy across a spectrum is theoretically predicted for the 3-site jump about the C$_3$ axis for the methyl group [5]. The temperature dependent T_1 of PMLA-d$_3$ is shown in Figure 2. T_1 values increase linearly with temperature from -125 to -40 °C, showing the fast motional region. The correlation time τ_c of the 3-site jump motion is estimated to be 15 ps at -95 °C, and an Arrhenius plot of τ_c yields an activation energy of 6.8 kJ/mol. These results imply that the methyl group bonded to oxygen atom experience a lower steric hindrance than a methyl group bonded to carbon atom, and support the view that the intermolecular contribution to the hindering barriers to the methyl group reorientation is relatively weak.

There are observable deviations from the linear Arrhenius plot behavior at above -40 °C, together with slight decreases in $\Delta\nu_q$, indicating the onset of new and rapid motions in the side chain. Conformational energy calculations of PMLA show the C$_3$ axis is trans and parallel to the C_β–C_γ axis in the side chain [6]. Therefore, the rotational motions about the C_β–C_γ axis little affect the line shapes of the methyl group and the line shapes observed at above 50 °C suggest the presence of large amplitude motions about the C_α–C_β axis. Since the reorientation about the C_α–C_β axis is allowed to a trans-gausch isomerization, the two-fold jump with equal population about the C_α–C_β axis and the effective quadrupole coupling constant of 50.7 kHz is assumed to calculate line shapes. The calculated spectra, which are in good agreement with the observed, indicate the averaged jump angle of 110° with the standard deviation of 5° in a Gaussian distribution of jump angle, and the jump rate of the order of kHz.

Figure 1(b) shows the temperature dependent spectra of the right-handed α-helical poly(γ-[$^2H_3$]methyl L-glutamate)(PMLG-d$_3$) [7,8]. The side chain length of PMLG is longer by a methylene group than that of PMLA. Similar line shapes are obtained for both PMLG-d$_3$ and PMLA-d$_3$, although line shapes of PMLG-d$_3$ become sharper and a singlet above 100 °C. These results indicate the presence of large amplitude motions with a rate of 40 kHz order in addition to the C$_3$ motion.

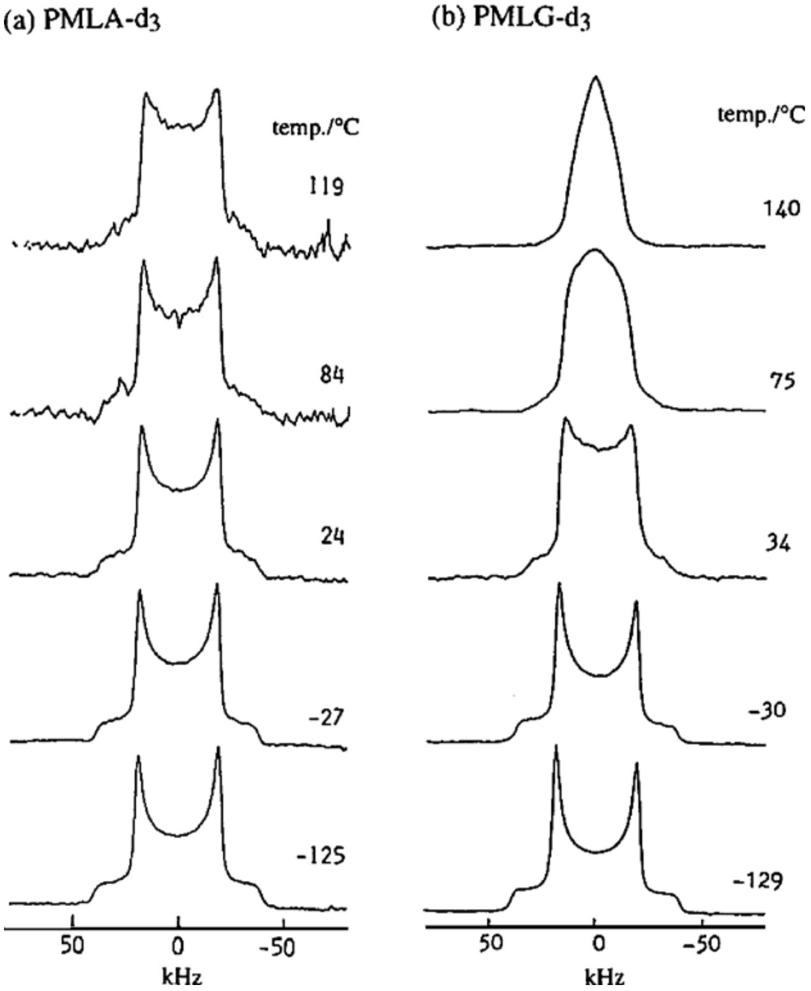

Fig. 1. ^{2}H NMR spectra of PMLA-d_3 (a) and PMLG-d_3 (b) as a function of temperature. Spectra were taken by a quadrupole echo pulse sequence with 90° pulse of 1.7 μs and delay of 25 μs at 30.7 MHz.

The temperature dependent T_1 of PMLG-d_3 is shown in Figure 2. T_1 anisotropy is as well observed in PMLG-d_3 at below 20 °C, showing the 3-site jump motion [5]. An Arrhenius plot of τ_c for the 3-site jump gives an activation energy of 7.5 kJ/mol, which is comparable with that of PMLA-d_3. The maximum and minimum of T_1 are observed at about 10 and 130 °C, respectively, with increasing a temperature. These results indicate additional motions of the C_3 axis along a side chain. One can easily estimate a correlation time of such motions to be about 5 ns at 130 °C from T_1 minimum. As T_1 minimum was observed at 100 °C for PMLG deuterated in the γ-position, these motions are present along a side chain as a whole.

Phenyl Ring

Phenyl ring motion in β-form poly(L-phenylalanine) (PLF-d_5) are displayed as a function of temperature in Figure 3 [9]. There are two categories of deuterons on a phenyl ring. Those on *ortho* and *meta* sites are affected by any rotational motions about the C_β–C_γ axis. The *para* site is essentially unaffected by motions about this

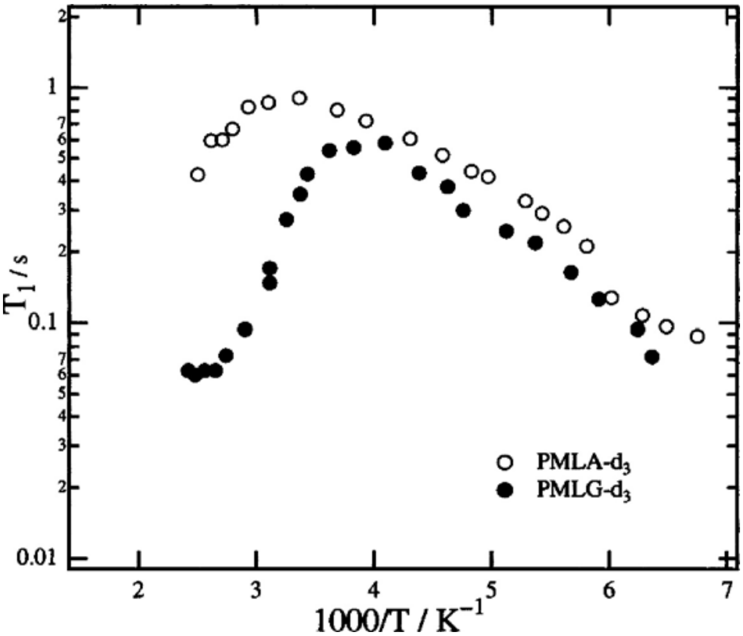

Fig. 2. Temperature dependent T_1 of PMLA-d$_3$ and PMLG-d$_3$.

axis, and its line shape exhibits a rigid powder pattern. As the unaffected *para* line shape is superimposed on the line shape of the other ring deuterons that contain the dynamic information of interest, line shapes of a phenyl ring shows that effects of motions are heterogeneous. Such motional heterogeneity results in different T_1 values, allowing the separation of the components using the amorphous quadrupole echo [10].

The line shape of PLF-d$_5$at -100 °C reveals a nearly rigid powder pattern and the small inner singularities with $\Delta\nu_q$ of 32 kHz are observed in the center of the spectrum. This grows in amplitude at the expense of the relative intensity of the rigid pattern as temperature is raised. These signals are present at all temperature measured from -100 to 65 °C, indicative of the π-flip motion of the ring about its symmetry axis [5]. There is no substantial change in line shape from 65 to 140 °C. As additional narrowing can not be observed in line shape, large amplitude motions about the C_α–C_β axis could be excluded.

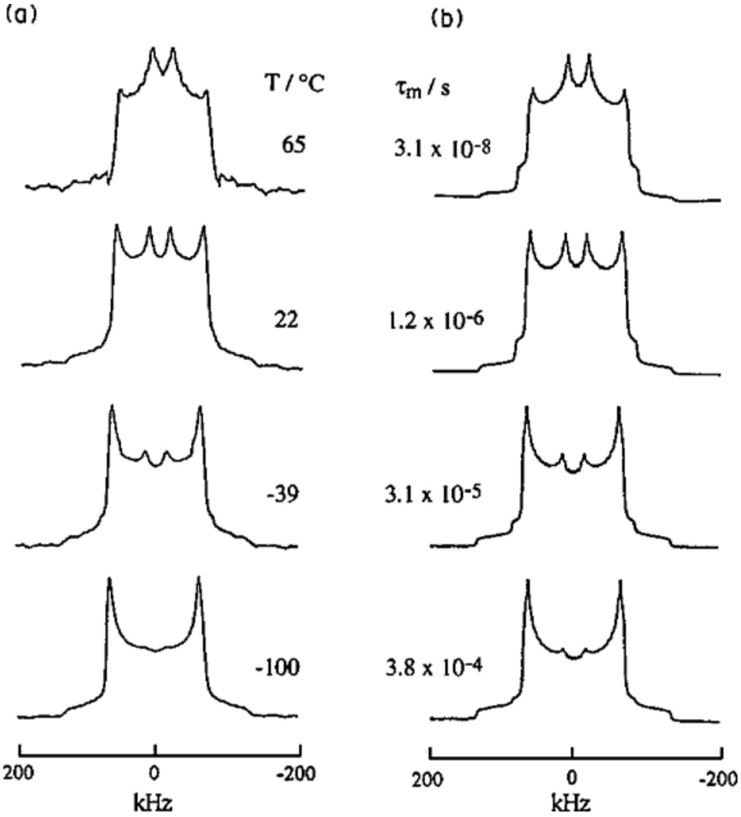
Line shapes are calculated with an assumption of a log-Gaussian distribution of the correlation time of the π-flipping [11,12], as shown in Figure 3. The calculated spectra are in good agreement with the observed. The mean correlation time obtained at 22 °C is estimated to be 1.2×10^{-6} s and an Arrhenius plot of the mean correlation time yields an activation energy of 28 kJ/mol. Such low activation energy exhibits less hindrance of rings. As PLF-d$_5$ is in the β-form and rings protrude from the β-sheet, the inter- and intra-interaction between side chains would significantly have the motional freedom for the flipping motion.

Side Chain of Poly(γ-benzyl L-glutamate) (PBLG)

Three positions along a side chain of PBLG are deuterated at γ(PBLG-γd_2), ζ(PBLG-ζd_2), phenyl ring(PBLG-d$_5$) [8,13–15]. PBLG forms a right-handed α-helical conformation. The side chains are located between the pseudo-hexagonally packed α-helical rods in solid [16,17]. Rapid and large amplitude motions of the side chain are prominent above room temperature, and, therefore, these dynamics results in the behavior like the glass transition of the PBLG side chains around room temperature [8,15].

The temperature dependent ^{2}H NMR spectra of PBLG-d$_5$ are shown in Figure 4. The typical line shape for the rapid π flipping motion of a phenyl ring about the C_ζ–C_η axis is observed at 20 °C, although line shapes below -76 °C are similar to the rigid state pattern. The spectrum at 20 °C has $\Delta\nu_q$ of 26 kHz which is smaller by 4 kHz than the flipping, indicating the presence of the libration. The amplitude of the libration is estimated with

Fig. 3. Temperature dependence of observed (a) and calculated (b) spectra of PLF-d_5. Figures on the right- and left-hand sides of spectra indicate the temperature and the mean correlation time, respectively.



the diffusion in a cone of semiangle θ_C to be 28° at 20 °C. The line shape remarkably changes with a further increase in temperature and a motionally averaged singlet spectrum with the half-width of 10 kHz is observed at 130 °C. These results show that the flipping axis itself undergoes rapid and large amplitude motions, in addition to the flipping motion and the small amplitude libration. This flipping-axis motion definitely results from the multiple internal rotations along the side chain above the glass-like transition temperature.

The temperature dependence of the integrated intensities of PBLG-d_5 spectra is shown in Figure 5. The intensity decreases with an increase in temperature and achieves a minimum at -40 °C. It decreases again and exhibits the deep minimum at 50 °C. The temperature regions where the intensity takes a minimum, corresponding that the rate of the motion is as high as the quadrupole coupling constant of 180 kHz in these temperature regions. Taking account of the line shape changes, the minima at the lower and higher temperatures are expected to correspond to the flipping motion of a phenyl ring and the motion of flipping axis itself, respectively.

Line shapes are calculated for the flipping motion with assuming a distribution of a jump rate [11,12], and compared with the observed. The average jump rate obtained is 2.3×10^5 Hz at 20 °C. This result is comparable with the appearance of the minima for the intensities. The activation energy of the flipping is obtained to be 23 kJ/mol below 30 °C.

Spectra of PBLG-ζd_2 will give direct information about the motion of flipping axis itself, because the C_ζ–^{2}H axis and the C_ζ–C_η axis have a common motional axis of the O_ε–C_ζ bond. The line shape and the intensity of PBLG-ζd_2 are displayed in Figures 4 and 5, respectively. The line shape at 20 °C is slightly different from a static powder pattern. The parallel components of the spectrum is not clear and the center of the spectrum is more filled-in than the static one. $\Delta\nu_q$ is slightly smaller than the rigid state value of 128 kHz, and decreases gradually with increasing temperature. These results suggest that there is a rapid and small amplitude libration at the ζ position. The integrated intensity of PBLG-ζd_2 start to decrease gradually from the lowest temperature to room temperature, and a remarkable intensity loss is observed around 50 °C.

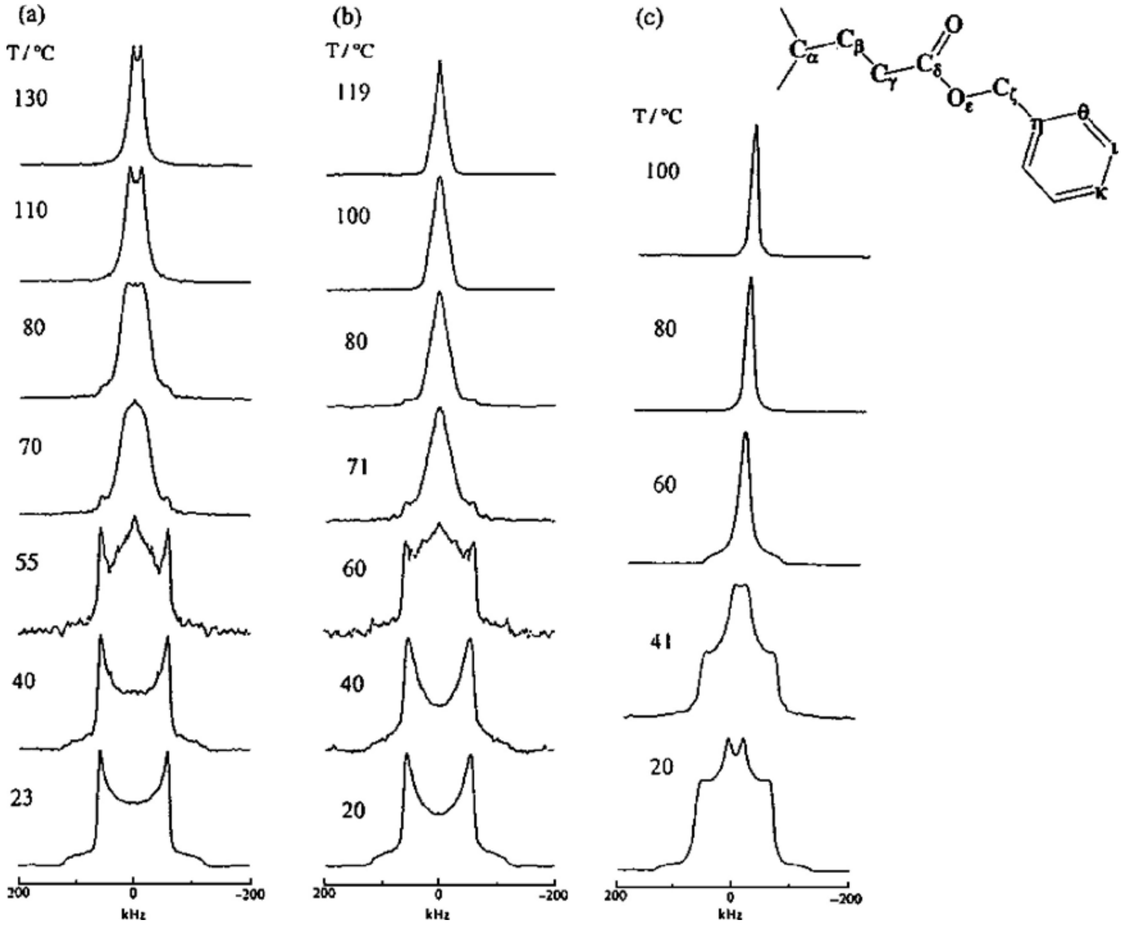


Fig. 4. ^{2}H NMR spectra of PBLG-γd_2(a), PBLG-ζd_2(b), and PBLG-d_5(c) as a function of temperature, and skeletal structure of PBLG side chain.

With a further increase in temperature, the spectrum recovers its intensity. Above 80 °C the motionally averaged singlet-like spectra are observed, showing that the presence of rapid and large amplitude motions of which frequency is as high as 100 kHz around 50 °C and becomes far higher above 80 °C. The remarkable τ-dependence is observed around 40–60 °C, being consistent with the remarkable intensity loss [15].

Temperature dependent T_1 of PBLG-ζd_2 is shown in Figure 6. T_1 value decreases gradually with an increase in temperature, and start to decrease steeply from room temperature. T_1 value takes a minimum at 110 °C, showing the presence of the large amplitude motions of the side chain whose rate is as high as the observed frequency of 30 MHz at this temperature. The temperature dependent T_1 can be apparently divided into two regions by room temperature. Therefore, T_1 value will be governed by different motional modes of the side chain, that is, the libration and the large amplitude motions below and above room temperature, respectively, taking the temperature dependence of the line shapes into account. The large amplitude motions are brought about the multiple internal rotations along a side chain. Such motions are well formalized by the 3-site jump with a distribution of both a jump rate and a polar angle. Such calculations well produce line shapes and T_1 profiles of PBLG-ζd_2. Averaged jump rate and polar angle obtained at 110 °C are 64 MHz and 49°, respectively.

Temperature dependent spectra of PBLG-γd_2 and its intensity are shown in Figures 4 and 5, respectively. The line shapes below 30 °C appear to be an axially symmetric powder pattern, showing the absence of large amplitude

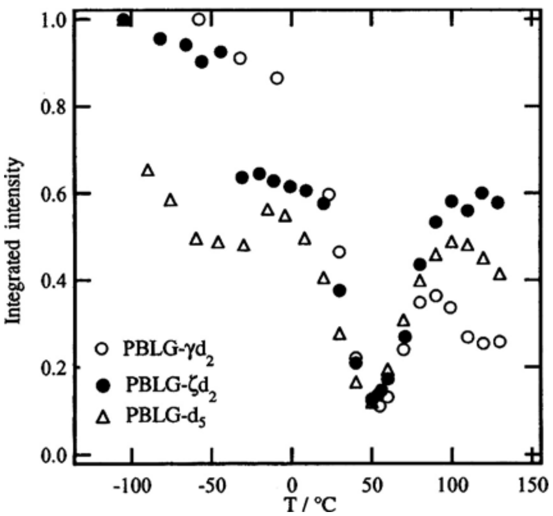

Fig. 5. Integrated intensity of PBLG-γd_2, PBLG-ζd_2, and PBLG-d_5 as a function of temperature.

motions. The $\Delta\nu_q$ value of 117 kHz at 20 °C is smaller than the rigid state value of 128 kHz, showing the presence of the fast small amplitude libration at the γ position, as observed at the phenyl ring and ζ position of the side chain. It decreases to 115 kHz at 60 °C. The intensity of the spectrum starts to decrease gradually and reaches a minimum value at 55 °C with an increase in temperature. Line shapes remarkably changes to start from about 40 °C and the characteristic line shape change is also observed around 55 °C. This intensity loss and the remarkable line shape change result from the increase in mobility, indicating the presence of the motion of which rate is the order of 10^5 Hz at the γ position. With a further increase in temperature, the spectrum recovers its intensity and gradually changes into the motionally averaged narrow doublet one whose splitting is 12 kHz at 130 °C. These results show the presence of the rapid and large amplitude motion at this position. The temperature dependence of the intensity for PBLG-γd_2 is quite similar to those of PBLG-d_5 and PBLG-ζd_2. In particular, the intensities of all these three samples take a minimum at the same temperature region, implying that the motions effective on the line shape changes of PBLG-γd_2 is also effective on the line shape changes of PBLG-d_5 and PBLG-ζd_2. These motions were conformed by ^{13}C CP/MAS NMR measurements [18].

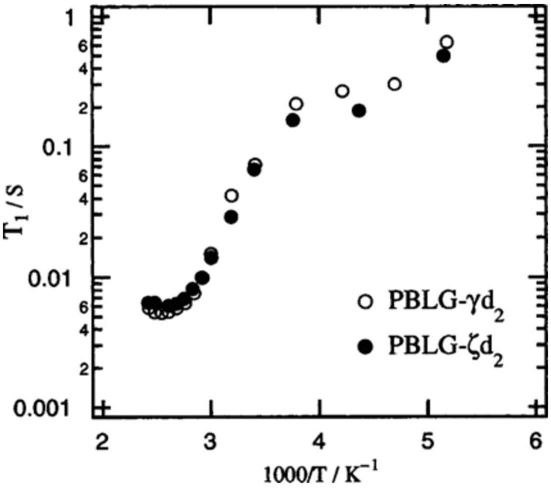

Fig. 6. Temperature dependent T_1 of PBLG-γd_2 and PBLG-ζd_2.

The temperature dependent T_1 of PBLG-γd_2 is shown in Figure 6. The T_1 profile of PBLG-γd_2 is very similar to that of PBLG-ζd_2. Especially in the high temperature region, T_1 values of both samples achieve the minimum at 110–120 °C. These results reveal that the common motional modes contribute to the T_1 values of remote positions in a side chain and/or that the motions at two different positions have a common motional rate. In the low temperature region, the T_1 values of PBLG-γd_2 are a little longer than those of PBLG-ζd_2, suggesting that the libration at the γ position is more restricted than that at the ζ position. In order to confirm the large amplitude motions at the γ position quantitatively, the spectral simulation was carried out. The methodology is the same as that used for PBLG-ζd_2. The parameters obtained are the polar angle of 45° and the averaged jump rate of 64 MHz at 110 °C, and suggest that the segmental motion including at least the γ position to the end of side chain participate in the glass-like transition phenomenon.

Main Chain Dynamics

The line shapes and T_1 values of the amide deuteron of α-helical PBLG were measured over a wide temperature range [19]. As the temperature is raised, the components of EFG tensor along the axis and perpendicular to the peptide plane decreases, whereas the mutually orthogonal components remain constant. Thus, the N–^{2}H axis undergoes the libration with 5 ps at 16 °C, showing the reorientation in the hydrogen-bonded peptide plane. And the amplitude of the libration is estimated to be from 8 to 12°.The short T_1 values of the N–^{2}H axis result from substantial frictional effects on reorientation that increase with temperature. The similar results were obtained for the amide deuteron of PMLG [20].

Polyglycine (PG) takes two kinds of crystalline forms designated by type I(β-form) and II (3_1-helix) [21]. Line shapes of both PGs deuterated in backbone methylene group remains the axially symmetric powder patterns with $\Delta\nu_q$ of 119 kHz at $-80\,^\circ$C–114 kHz at 125 °C, indicating the libration with the amplitude of 12°–15° [22,23]. T_1 values of both PGs decrease with increase in temperature, and T_1 values of PG I are shorter than those of PG II. These results show that the reorientation of the backbone in the regular secondary structure, which contains directly the hydrogen bond, is subject to a harmonic restoring force and that the motional modes are strongly overdamped [19].

The backbone dynamics is subsequently modulated by replacing partly the methyl group of PMLG by the long side chain of stearyl group [20]. Line shapes and T_1 values of these copolypeptides are remarkably changed above the melting temperature of the long side chain crystal. These results show the presence of the rotational reorientation about the helical axis of the copolypeptides, as well as the libration of the peptide plane. The rotational angle of 55° with the rate of kHz order for such a motion is obtained from the line shape calculation.

Polymer Blends

Polymer Blends

Atsushi Asano
Department of Applied Chemistry, National Defense Academy, Yokosuka, Kanagawa 239-8686, Japan

Overview

Macroscopic properties of polymer blends are influenced by the degree of mixing among component polymers, that is, microscopic domain structure. The degree of mixing is related to how closely we look at the blend. The lower limitation of a characteristic space scale of a particular observation determines the detectable domain size in a miscible state, and affects the judgment of homogeneity. For most miscible polymer blends, in general, a single homogeneous phase is achieved by an interpolymer interaction and separates to two phases with distinct compositions and becomes heterogeneous when the temperature is beyond a critical point. Solid-state NMR provides very useful information to detect such a microscopic compositional change, especially less than 10–100 nm scale. Here, the interpolymer interaction, miscibility, and phase separation are mainly touched upon.

Interaction in Polymer Blends

It is necessary for polymer pairs to be miscible on a molecular level that the Gibbs free energy of mixing becomes negative. In general, the exothermic exchange polymer–polymer interaction assists for the free energy to be negative at a certain temperature: the phase diagram shows the lower critical solution temperature (LCST). The polymer–polymer interaction frequently affects solid-state NMR spectrum [1]. By comparing the spectrum of each component polymer with that of a blend, some changes in a chemical shift and/or a lineshape can be easily detected. Among several interactions, the hydrogen-bonding interaction causes appreciable change in a spectrum.

Figure 1 shows the expanded observed solid-state ^{13}C NMR spectra of poly(methyl methacrylate)/poly(vinyl acetate) (PMAA/PVAc) blends at the carboxyl/carbonyl (C=O) region [2]. The simulated spectra for blends obtained from the simple sum of each observed ^{13}C NMR spectrum of pure PMAA and pure PVAc at the respective molar ratio are also displayed in the right side. At the left side, decomposed spectra obtained from the least-square fit to the observed ^{13}C NMR spectra by a sum of five Gaussian curves are summarized.

The broad COOH line of pure PMAA is observed at 183 ppm and the narrower COO peak of PVAc is at 171 ppm. If there is no polymer–polymer interaction between the side chains of PMAA and PVAc, the observed NMR spectra should be reintroduced by the simple summation. However, the observed spectra of the PMAA/PVAc blends are obviously different from the simulated spectra. The observed spectra have a much more complicated envelope. The lineshape of the CO region in the blends seems to be divided into apparently five peaks. Two peaks at around 187 and 179 ppm of those five peaks are clearly appeared, especially, in the spectrum of the PMAA/PVAc = 1/1 blend. A peak at around 175 ppm is also clearly seen in the spectrum of the PMAA/PVAc = 3/1 blend, while the peak at 175 ppm for the other blends are disappeared behind the broad envelope. These observations clearly suggest the existence of an interpolymer interaction. It is revealed that the peak at 179 ppm is attributed to the PMAA-COOH carbon which the carboxylic hydrogen is interacted with PVAc-CO oxygen, and the PVAc-CO carbon peak is appeared at 175 ppm by observations of composition dependence of the ^{13}C spin–lattice relaxation time [2] and two-dimensional (2D) exchange ^{13}C NMR [3]. The abundant 2D exchange ^{13}C NMR spectrum clearly showed the cross-peaks between at $\omega_1 = 175$ ppm and $\omega_2 = 179$ ppm and between $\omega_1 = 179$ ppm and $\omega_2 = 175$ ppm with the same peak intensity [3]. This observation proved that the distance between the interacted PMAA-COOH carbon and the PVAc-CO carbon is 0.37 nm. The length of hydrogen bond was also estimated from the molecular mechanics calculation to be ca. 0.2 nm.

Similarly to the example shown in Figure 1, each component polymer in a miscible polymer blend is in close proximity to interact with each other. The short distance less than about 0.5 nm can be also observed via the nuclear Overhauser effect (NOE). The ^{1}H NOE cross-peaks were observed between 1,2-polybutadiene and polyisoprene of their blend from the 2D NOESY spectrum in solids [4]. For a deuterated-polystyrene (d-PS)/poly(vinyl methyl ether) (PVME) blend, the ^{1}H–^{13}C NOE was detected between the ^{1}H spins of PVME and the ^{13}C spins of d-PS in solids [5,6]. Furthermore, the close proximity caused by a polymer–polymer interaction also affects

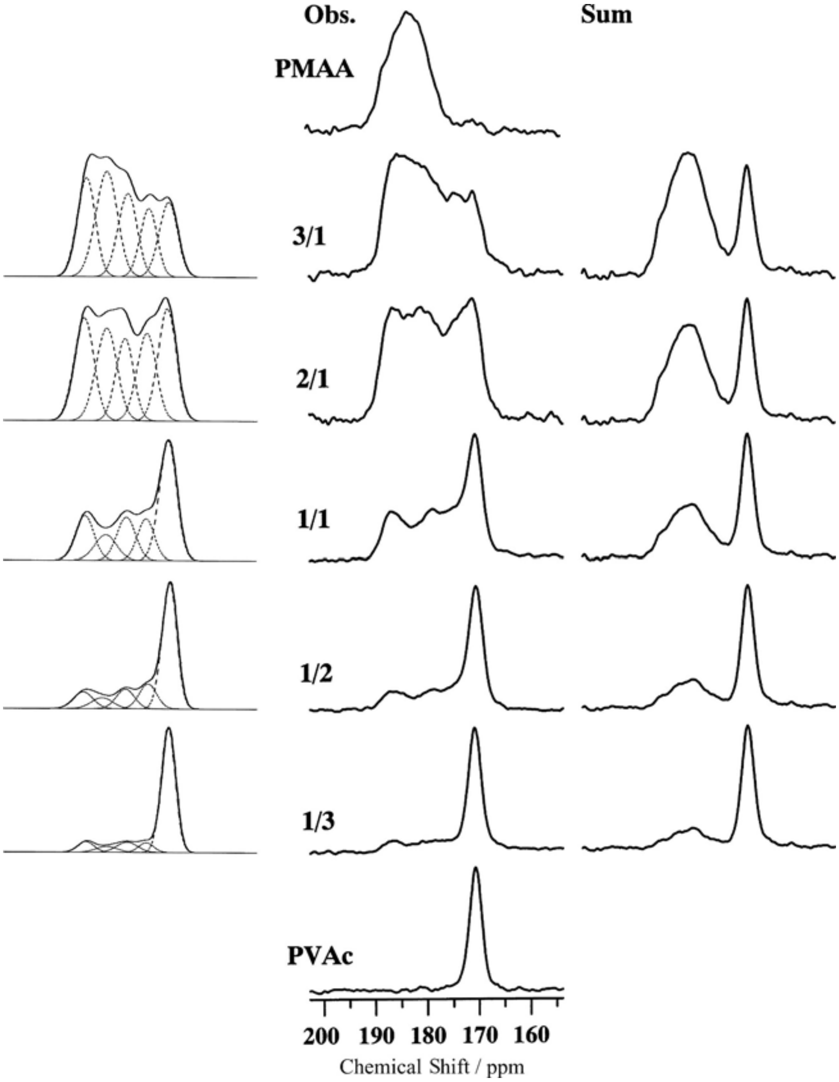

Fig. 1. Expanded observed CPMAS ^{13}C NMR spectra (center) and the decomposed simulated spectra using five Gaussian curves (the left hand) of the CO region in the PMAA/PVAc blends: a broken line depicts each decomposed peak and a solid line is the sum of those broken lines. Sum of the ^{13}C NMR spectra of pure PMAA and pure PVAc at the respective molar unit ratio is also drawn on the right hand of the observed spectra.

molecular motion [1]. The change of molecular motion is revealed from ^{13}C spin–lattice relaxation [7], 2D exchange NMR [8], deuterium NMR [8,9], and ^{13}C lineshape experiments [10,11].

Similarly, the domain size from 10 to 100 nm is revealed through ^{1}H or ^{13}C spin-diffusion phenomena [12,13]. The ^{1}H spin diffusion largely affects the ^{1}H relaxation rate in the homogeneous blends, thus the observation of ^{1}H relaxation reveals the domain size, namely miscibility.

Miscibility

Two kinds of domain sizes are easily detected through both ^{1}H spin–lattice relaxation times in the laboratory

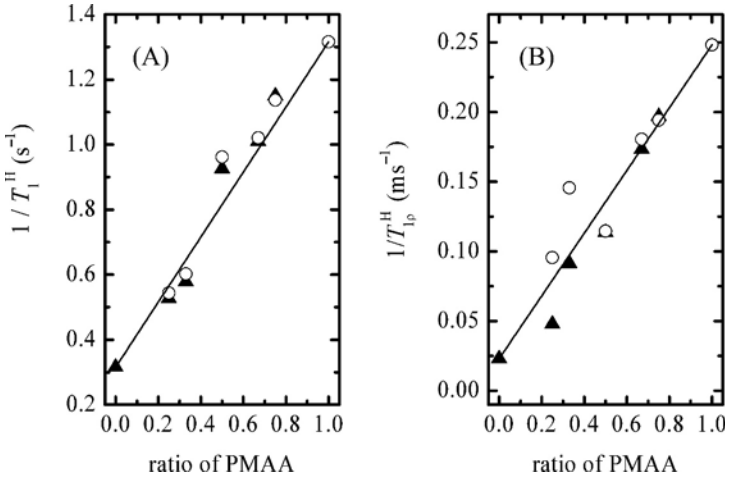

Fig. 2. Observed $1/T_1^{\mathrm{H}}$ (A) and $1/T_{1\rho}^{\mathrm{H}}$ (B) values, namely the ^{1}H relaxation rates, against the ^{1}H molar unit ratio of PMAA/PVAc blends: ○ CH_2 carbon of PMAA, ∫▲ OCH carbon of PVAc, and each solid straight line represents the calculated one from Equation (1). Every error bar for each data point is covered with the symbols itself. In this case, PMAA weight ratio of the blends is equivalent to that of ^{1}H mole fraction because both unit weight and number of protons in a unit structure of PMAA [–($CH_2CCH_3(COOH)$)–] are the same as those of PVAc [–($CH_2CH(OCOCH_3)$)–].

(T_1^{H}) and the rotating frames ($T_{1\rho}^{\mathrm{H}}$) [1]. In the solid state, the fast ^{1}H spin diffusion averages various spin temperatures of almost all protons in a polymer. As a result each ^{1}H relaxation time obtained from the every well-resolved ^{13}C peaks has the identical value. A similar criterion holds on a homogeneous polymer blend. The fast ^{1}H spin diffusion among component polymers causes to equalize the distinct ^{1}H relaxation times of components. On the other hand, in a heterogeneous blend, each individual ^{1}H relaxation time of component polymers is not fully averaged because the large domain size does not allow to average entirely the individual ^{1}H spin temperature; the intrinsic ^{1}H spin-diffusion rate is the same as that in the homogeneous phases, when the domain size is larger than the maximum diffusive path length, in such a case, the apparent ^{1}H spin-diffusion rate (cross-relaxation rate) becomes slow. On the other hand, even in a homogeneous polymer blend, there is a case that the intrinsic ^{1}H spin-diffusion rate becomes slower. In general, such a case is called as a motional heterogeneity: the miscible PS/PVME blend is a typical case [14].

Figure 2A shows that both original T_1^{H} rates of pure PMAA and pure PVAc are averaged to the values depended on the compositions in the blend. All the obtained T_1^{H} rates of PMAA in the blends are in excellent agreement with those of PVAc. This indicates that the complete averaging of the T_1^{H} rates by ^{1}H spin diffusion occurs, suggesting that PMAA and PVAc are in close proximity with each other and the PMAA/PVAc blend is homogeneous on a scale of 20–50 nm for all compositions. Similarly, Figure 2B shows that the observed $T_{1\rho}^{\mathrm{H}}$ rates of PMAA in the PMAA-rich/PVAc blends, which are the PMAA/PVAc $= 3/1$, $2/1$, and $1/1$ blends, are fully consistent with those of PVAc. For the PMAA-poor (PMAA/PVAc-rich) blends, which are the PMAA/PVAc $= 1/2$ and $1/3$ blends, however, the $T_{1\rho}^{\mathrm{H}}$ rates of PMAA are different from those of PVAc, although both rates of PMAA and PVAc change together and become close. This indicates that the partially averaging of $T_{1\rho}^{\mathrm{H}}$ rates by ^{1}H spin diffusion occurs in the PMAA/PVAc-rich blends. These results show that the PMAA-rich/PVAc blends are homogeneous on a scale of 2–5 nm as well as 20–50 nm, but the PMAA/PVAc-rich blends are inhomogeneous on the scale. The PMAA/PVAc-rich blends are probably homogeneous on a 5–10 nm scale, because the $T_{1\rho}^{\mathrm{H}}$ rates are affected largely by ^{1}H spin diffusion.

If the ^{1}H spin diffusion among the component polymers is fast sufficiently and the change of molecular motion by blending is negligible, the apparent relaxation rate $K_{\mathrm{ave}}(= 1/T_{1\mathrm{ave}})$ is given as a ^{1}H mole weighted average of the original rates of pure component polymers, K_{X} and K_{Y} as

$$K_{\mathrm{ave}} = f_{\mathrm{X}} K_{\mathrm{X}} + (1 - f_{\mathrm{X}}) K_{\mathrm{Y}}, \tag{1}$$

where f_{X} is ^{1}H mole fraction of polymer X in a polymer blend X/Y. The solid straight lines in Figure 2A and B represent the calculated values using the above Equation (1).

The observed T_1^{H} rates are in good agreement with the calculated ones. Similarly, the observed $T_{1\rho}^{\mathrm{H}}$ rates for PMAA-rich blends are consistent with the calculated ones. These agreements indicate that the molecular motions of both polymers in the blends are not changed drastically with each other comparing with those before mixing, and the very fast ^{1}H spin diffusion is occurred in the blends.

The partially miscible state and the motional heterogeneity of polymer blends can be investigated by analyzing the ^{1}H relaxation decay curves. When the apparent ^{1}H spin-diffusion rate (k_c) is comparable to the $1/T_1$, the T_1 decay curves deviate from a single exponential. The estimate ^{1}H spin-diffusion rate directly reveals the maximum average diffusive domain size (x) from the equation of $x^2 = 6D/k_c$ if the ^{1}H spin-diffusion constant (D) is known [1,15,16]. Similar ^{1}H relaxation decay curves are also observed in a case of the motional heterogeneity [14,17]. However, the non-exponential decay curves only appear when the experimental temperature is higher than T_g. The T_1 measurements at lower than T_g give a single-exponential decay for both polymers X and Y. This is the remarkable feature of the motional heterogeneity. In most miscible blends, the k_c is extremely fast and the ^{1}H relaxation curves become identical, even though the blends are partially homogeneous. The identical and single-exponential decay for both polymers X and Y is realized when the value of k_c is 10–100 times faster than the fastest $1/T_1$ in the polymer blend X/Y [14].

Phase Separation Process

Homogeneous phase of a polymer blend for an LCST phase diagram is not thermodynamically much stable and easily collapsed, when the temperature is beyond the binodal point; this region is thermodynamically unstable. The homogeneous phase becomes heterogeneous and the transparent film, in general, changes into opaque. The concentration change during the spinodal decomposition at the initial stage was expressed by analyzing the ^{1}H spin–lattice relaxation [14,18].

Figure 3 shows a graphically illustrated model of a phase separation: the homogeneous polymer blend X/Y is phase-separated into the X-rich and the Y-rich domains after heat treatment. This model represents that the fast ^{1}H spin diffusion occurs within each domain in the phase-separated blend, that is, each X-rich and Y-rich domain is homogeneously mixed from the ^{1}H spin diffusion point of view, while there is no effective ^{1}H spin diffusion between the X-rich and Y-rich domains. This is because the distance between the X-rich and Y-rich domains becomes over 5 nm for $T_{1\rho}^{\mathrm{H}}$ or 50 nm for T_1^{H}: each homogeneous domain size is larger than 5 or 50 nm. Each domain has an individual ^{1}H spin–lattice relaxation time; the T_1 value of polymer Y in the X-rich domain is the same as that of polymer X, $T_{1\mathrm{X}}$. Similarly the T_1 value of those in the Y-rich domain is $T_{1\mathrm{Y}}$. According to this assumption, it is obvious that the relaxation curve observed from polymer X or Y shows a double-exponential decay [14,18]. The expected relaxation curves are

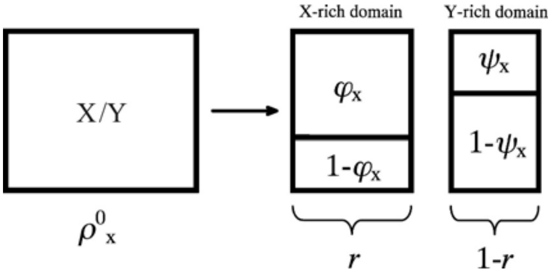

Fig. 3. Schematic illustration of phase separation model at the initial stage. A single homogeneous phase of a miscible polymer blend X/Y is phase-separated into two phases with which have the compositions of φ_{X} and ψ_{X}: the initial X fraction in the X/Y blend is represented by the symbol ρ_x^0. The symbol r shows the fraction of the X-rich domain.

$$M_{\mathrm{X}} = \xi_{\mathrm{X}} \exp(-t/T_{1\mathrm{X}}) + (1-\xi_{\mathrm{X}}) \exp(-t/T_{1\mathrm{Y}}) \qquad (2a)$$

$$M_{\mathrm{Y}} = \xi_{\mathrm{Y}} \exp(-t/T_{1\mathrm{X}}) + (1-\xi_{\mathrm{Y}}) \exp(-t/T_{1\mathrm{Y}}). \qquad (2b)$$

Here, M_{X} and M_{Y} represent the magnetization: in the case of the inversion–recovery method, M_{X} equals to $\left\{M_{\mathrm{Z}}^0 - M_{\mathrm{X}}(t)\right\}/2M_{\mathrm{Z}}^0$ and to $M_{\mathrm{X}}(t)/M_{\mathrm{Z}}^0$ in the case of the ^{1}H spin-locking experiment, M_{Z}^0 is the equilibrium magnetization. The parameters ξ_{X} and ξ_{Y} are ^{1}H mole fractions of polymer X and Y of whole blend, respectively; $\xi_{\mathrm{X}} = \varphi_{\mathrm{X}} r/\{\varphi_{\mathrm{X}} r + \psi_{\mathrm{X}}(1-r)\}$ and $\xi_{\mathrm{Y}} = (1-\varphi_{\mathrm{X}})r/\{(1-\varphi_{\mathrm{X}})r + (1-\psi_{\mathrm{X}})(1-r)\}$, respectively, with $\varphi_{\mathrm{X}} r + \psi_{\mathrm{X}}(1-r) = \rho_x^0$: φ_{X} and ψ_{X} are concentration of each domain. Thus, the stoichiometry φ_{X} and ψ_{X} of the two separated phases and r, which is the fraction of the X-rich domain, are easily deduced from the fractions of Equations (2a) and (2b). The φ_{X} or ψ_{X} are any of ^{1}H mole/weight/volume fractions. They are depended on how one determines the ρ_x^0 value.

Figure 4 shows the observed $T_{1\rho}^{\mathrm{H}}$ decay curves of the PS/PVME = 1/1 blend ($\rho_x^0 = 0.5$), which is quickly cooled in liquid nitrogen to quench the phase separation progress after heating at 413 K for 2 min [14]. The $T_{1\rho}^{\mathrm{H}}$ decay curves are measured at 263 K to freeze the molecular motion of PVME and let the ^{1}H spin diffusion work effectively. Before heat treatment, both observed $T_{1\rho}^{\mathrm{H}}$ decays obtained from PS and PVME signals show the same single-exponential curve. With increasing the heat-treatment time, they deviate from a single exponential to show the double-exponential behavior. The solid lines in Figure 4 are the "best-fit" curves obtained from Equations (2a) and (2b). The adjusted values for ξ_{X} and ξ_{Y} are 0.20 ± 0.03 and 0.81 ± 0.05, respectively, and $T_{1\mathrm{X}}$ and $T_{1\mathrm{Y}}$ are 3.1 ± 0.2 and 15.3 ± 0.6 ms. The estimated values for φ_{X}, ψ_{X}, and r are 0.20 ± 0.03, 0.81 ± 0.06, and 0.51 ± 0.04, respectively. The experiment with changing the heat-treatment time showed that the heating time-dependent fluctuation in concentration occurs

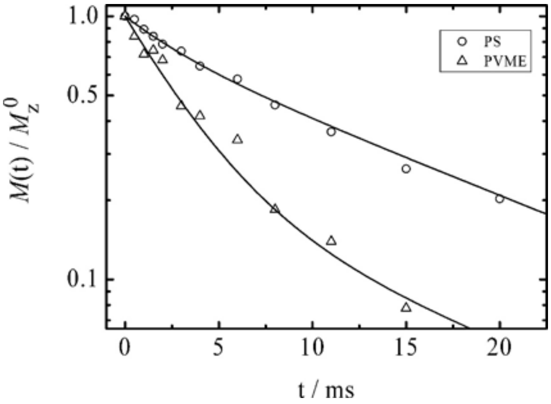

Fig. 4. Observed $T_{1\rho}^{\mathrm{H}}$ decay curves for PS (|) and PVME (∫) in the phase-separated PS/PVME = 1/1 blend after 2 min of heating at 413 K. These decay curves were measured at 263 K. The solid lines are the "best-fit" curves from Equations (2a) and (2b) with the parameters of $\xi_X = 0.20 \pm 0.03$, $\xi_Y = 0.81 \pm 0.05$, $T_{1X} = 3.1 \pm 0.2$ ms, and $T_{1Y} = 15.3 \pm 0.6$ ms.

and further heating over 30 min does not cause appreciable changes to the $T_{1\rho}^{\mathrm{H}}$ curves. This indicates that the initial stage of phase separation, that is the concentration change, finished and the morphological change occurs on a larger scale that is not reflected in T_1. The growth of domain size at the late stage of the phase separation of the PS/PVME blend has been revealed from the 2D exchange ^{129}Xe NMR [19]. The 2D exchange ^{129}Xe NMR showed that the cross-peaks observed after heating 30 min do not appear after 1200 min. The estimated average domain size is over 5000 nm at least.

Conclusion Remarks

The numerous great pioneering NMR works for polymer blends are omitted. We know the novel NMR techniques are applying to reveal the conformational change [20] and domain structure [21] and a lot of successful works can be found in any publications. The reader's attention is also drawn to the other reviews summarizing the miscibility or the molecular motion for polymer blends [1,22–24].

Configurational Entropy and Polymer Miscibility: New Experimental Insights From Solid-State NMR

Jeffery L. White*
North Carolina State University, Raleigh, NC 27695, USA

Abstract

Entropy is generally discounted as a driving force for macromolecular mixing, due to the vanishing combinatorial component in the Flory–Huggins treatment. However, recent chain-level investigations in blends of high molecular weight polyolefins suggest that configurational entropy must be considered, particularly for amorphous macromolecules lacking any chemical functionality. Multinuclear one- and two-dimensional solid-state NMR techniques were used to interrogate the dynamics and mixing length scales in blends containing polyisobutylene and either head-to-head polypropylene or polyethylene-co-butene. These polymer systems have no chemical heterogeneity that would facilitate miscibility through enthalpic contributions; experimental results prove that there is a quantifiable increase in configurational entropy. In addition, experimental evidence from polyolefin blends regarding the length-scale and time-scale of the polymer glass transition is discussed.

Introduction

Miscible polymer blends represent an important class of academic, technological, and commercial materials. An excellent recent reviews comprehensively addresses the subject of polymer blend miscibility [1]. However, in almost all of the published work on miscible macromolecules, the component polymers themselves contain chemically heterogeneous functional groups. For example, mixtures of polyacrylates and polyols (like polyvinylalcohol or polyvinylphenol) contain potential hydrogen bonding pairs, and therefore one would predict that an energetically favored miscible state would result due to a finite negative enthalpy of mixing [2]. Indeed, constituent polymers do not even have to contain polar atom substituents to be categorized as "functional" polymers. As an example, many miscible polymer mixtures containing olefinic or styrenic moieties are known to exist; even though the constituent atoms are all carbon or hydrogen, large electron density gradients exist within the macromolecule based on the differential amounts of sp, sp^2, and sp^3 carbons [3]. Consequently, their appreciable polarizability gives rise to induced dipole interactions that again drive mixing via an ethalpic contribution. Therefore, one might ask what happens when the constituent polymers are both chemically and electronically homogeneous, e.g. in completely saturated hydrocarbon polymers? Does one's intuition regarding enthalpic and entropic contributions to the overall free energy of mixing still serve as a useful guide?

Saturated hydrocarbon polymers, or polyolefins, are the most ubiquitous of polymer families. It is surprising that such architecturally simple/similar polymers, devoid of any functional groups, exhibit fairly complex phase behaviors. That polypropylene and polyethylene are immiscible at the chain level is by now well known; the reason why is still a controversial subject. The absence of polar functional groups in polyolefins essentially eliminates any significant enthalpic contributions to the free energy of mixing. Such "heats of mixing," typically represented by the enthalpic interaction term χ in Flory–Huggins theory, are commonly regarded as the driving force for miscibility. Dispersive forces via weak van der Waals interactions are possible, and may be significant for large molecular weight molecules. Entropic contributions to miscibility in polymer blends are usually discounted in the polymer blend literature, since molecular weights are large and Flory–Huggins theory scales entropy of mixing according to the inverse of the degree of polymerization. The question remains as to how mutual solubility in polyolefin blends depends on polymeric microstructure, tacticity, comonomer incorporation, and chain dynamics, and further, how each of these architectural and physical characteristics contributes to the interplay between enthalpy and entropy. Clearly, one would expect that the details of interchain packing and reorientation would be critically dependent on the aforementioned structural details. The current state of understanding in this area is nicely summarized by Graessley and coworkers [4]. In reviewing, the various data that supports enthalpy vs. entropy as driving forces, these authors note that several

© 2008 *Springer.*

researchers have proposed either as controlling factors, and some theoretical work suggests any combination of these two thermodynamic variables could lead to the observed phase behaviors. Further, the authors state that uncertainty centers around the interpretation of solubility parameters from SANS data and the anomalous behavior of many blends whose mixing does not follow the theoretical expectations from solubility parameter formalisms. The authors suggest that the key experimental data for local monomeric scale interactions are not accessible, and therefore simulations have been used. In a companion paper, these same authors propose some tentative ideas surrounding packing effects in copolymers vs. homopolymers, and how this might contribute to blend mixing [5]. Our recent research has focused on obtaining direct experimental data that address these conceptual holes. Spiess and Schmidt-Rohr nicely summarize our motivation in this area in their text *Multidimensional Solid-State NMR of Polymers,* which states: "Miscibility is often attributed to favourable specific interactions between the polymer components. However, simple geometric effects, such as unfavourable packing in one of the pure components that causes the molecules to prefer the packing in the mixture, also must be considered. The elucidation of these factors, which are often not directly apparent from the chemical structures, is still at an early stage. Modern solid-state NMR methods promise to play a major role in this field" [6].

Our initial work has targeted binary polyolefin blends that contain polyisobutylene (PIB) as one component. We have selected this approach due to literature reports of the anomalous behavior (large negative interaction parameters) of blends containing PIB at the time we began the project [7–9]. The resulting experimental data were the first to provide molecular/chain level evidence indicating that configurational entropy is a driving force for miscibility in polyolefin blends [10–12]. While standard Flory–Huggins theories discount entropy as a contributing factor in macromolecular mixing, our results do not contradict this conventional wisdom, in that combinatorial entropy (Flory–Huggins) is distinct compared to configurational entropy. Traditional theories of macromolecular mixing simply do not treat the polymer at the local chain (monomeric) level, which is where our experimental efforts focus. Indeed, many theoretical studies have recognized that configurational entropy must be an important contributor to polymer phase behavior [13–16]. In addition, some experimental studies have addressed the local structure and dynamics of functional polymer blends in the context of calorimetric and spectroscopic data [17,18]. However, to our knowledge, our work is the first to use solid-state NMR to interrogate the details of mixing in amorphous polymers lacking chemical heterogeneity, i.e. polyolefins, and quantitatively relate the data to configurational entropy.

Experimental NMR Methods

Solid-state NMR has addressed multiple questions regarding miscibility in polymer blends in recent years; methods ranging from simple chemical shift resolution to advanced multiple pulse/multiple quantum detection are by now routinely accessible. However, Figure 1 shows that the lack of any type of resolution in the ^{1}H solid-state NMR spectra of polyolefin blends complicates analysis of mixing length scales, dynamics, and chemical interactions in such systems even when coherent averaging pulse sequences are used. In particular, non-destructive spin-diffusion techniques are attractive since isotopic labeling is not a requirement, and recent developments in the understanding of spin-diffusion data has increased the

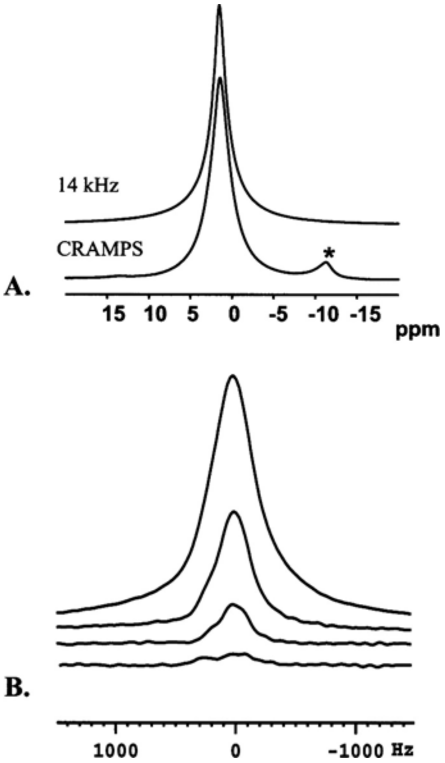

Fig. 1. (A) Comparison of ^{1}H CRAMPS experiment and fast magic-angle experiment on a 50:50 blend of PIB and hhPP, demonstrating the lack of resolved chemical shifts from either blend component using direct ^{1}H detection. (B) ^{1}H dipolar filter on PIB/PEB-66 blend at 23 °C as a function of the number of 12-pulse dipolar filter cycles, in which the interpulse spacing was 10 μs. From top to bottom, the number of filter cycles was 0, 10, 20, and 30, respectively.

quantitative accuracy of the method [19,20]. Figure 1A demonstrates the neither fast MAS nor CRAMPS [21] results in any chemical shift resolution of the aliphatic hydrogens in an amorphous polyolefin blend of PIB and head-to-head polypropylene (hhPP). Figure 1B shows ^{1}H MAS spectra obtained at 8 kHz for a PIB/PEB-66 (polyethylene-co-1-butene containing 66 wt% butene comonomer) blend, in which an additional dipolar filter sequence is applied prior to the read pulse in order to introduce spectral resolution based on gradients in the timescale of molecular motion in the two polymers [22]. Comparison of individual spectra in Figure 1B (in which the strength of the dipolar filter is increased in subsequent spectra) shows that this is not achieved experimentally, thereby eliminating the possibility of direct observation spin-diffusion methods. Results were identical for experiments without MAS, except that the line width was larger by a factor of 6–7. As one would expect, similar results were obtained for the higher-resolution ^{13}C-detected ^{1}H dipolar filter experiments, and Goldman–Shen techniques, thereby precluding the use of natural abundance spin-diffusion experiments as a quantitative tool for measuring length scales of mixing in these blends. Information regarding length scales of mixing in amorphous polymer blends is necessary to begin to determine governing thermodynamic parameters; Figure 1 and the preceding discussion show that tradition spin-diffusion methods often fail. We have found that a variety of experiments, ranging from those that probe dynamics on the timescales from seconds [two-dimensional (2D) exchange] to microseconds (relaxation and static ^{2}H NMR), as well as length scale measurements from angstroms to tens of nanometers (spin diffusion and Xe gas absorptions) are all required to obtain a consistent and thorough understanding of polyolefin phase behavior [10–12].

Choice of Polymer Blend System

Graessley and coworkers reported that the polyolefin blends which exhibited the largest net "attraction" or negative χ parameter were those prepared from PIB and hhPP, poly(ethylene-propylene), or polyethylene-co-butene (PEB) [7–9]. Such blends exhibited what the authors termed "irregular" mixing, in that the interaction parameter departs from description by a simple function of the difference in solubility parameters. The authors were not able to explain the origin of such a large interaction parameter for these anomalous miscible blends, but postulated it might arise from local packing constraints contributing to stronger "component pair" or intermonomeric interactions. In some cases, the mixing was found to be enhanced relative to that predicted from solubility parameters, while in others the mixing was reduced. Due to the anomalous behavior of these blends in which PIB was one component, and also considering the fact the PIB has a significantly higher bulk density than all amorphous polyolefins, we chose PIB-based blends as the our starting point for chain-level NMR studies. Space limitations will require that most of this chapter focuse on blends of PIB with PEB containing varying amounts of 1-butene comonomer in the PEB copolymer. These PEB copolymers will be denoted as PEB-XX, where XX represents the weight percent of butene comonomer, following the convention of Graessley and coworkers [7–9].

^{129}Xe NMR of Absorbed Xenon Gas

As stated above, traditional ^{1}H spin-diffusion techniques often fail for some polyolefin blends. While we successfully used spin diffusion to probe length scales of mixing in PIB/hhPP blends [23], they were not able to generate a polarization gradient in PIB/PEB-XX blends, as the differences in overall chain dynamics, and ^{1}H chemical shifts in the solid state, for PIB vs. PEB were too small. Even though polyolefin blends are chemically homogeneous, their differing densities and free volumes allow the highly polarizable Xe atomic nucleus to report on chain packing heterogeneity. Figure 2 demonstrates that

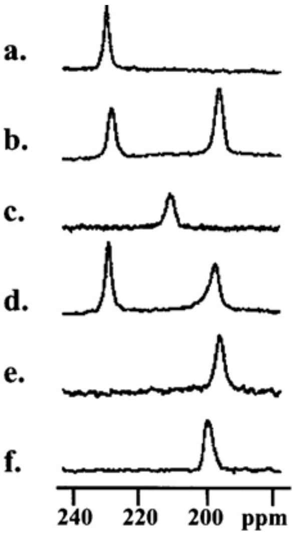

Fig. 2. Static ^{129}Xe NMR spectra for xenon gas absorbed in (a) pure PIB vs. blends with decreasing 1-butene comonomer amounts; (b) 50:50 PIB/PEB-97 blend; (c) 50:50 PIB/PEB-66 blend; (d) 50:50 PIB/PEB-23 blend; (e) pure PEB-97; and (f) pure isotactic poly-1-butene. The free xenon peak at 0 ppm is not shown for clarity, and lower sample masses were used in 2C and 2E.

simple one-pulse (static) Xe NMR experiments are remarkably sensitive to different polyolefin environments. In Figure 2, results are presented for ^{129}Xe chemical shift in pure PIB, pure poly-1-butene (P1B), and several blends. In contrast to all other blends of PIB with PEB or P1B, the PIB/PEB-66 blend (Figure 2c) shows only one resonance, indicating that the xenon molecule is diffusing in a homogenous molecular environment (as defined by the diffusion coefficient of xenon in that blend). For comparison, the PIB/PEB-23 blend shows two clearly resolved resonances (Figure 2d), corresponding very closely with the two pure component PIB and PEB-23 shifts. Here, xenon gas diffuses between two dissimilar surroundings, which match the two constituents, indicative of a much larger length scale of mixing, or domain size, relative to PIB/PEB-66 (vide infra). A similar microphase-separated result is obtained for a blend of PIB/PEB-97 (Figure 2b). Figures 2b–d reveal a compositional miscibility window in 1-butene concentration for blends of PEB with PIB. The data in Figure 2, coupled with quantitative pulsed-field gradient NMR to measure the Xe diffusion coefficient in pure PIB vs. PIB/PEB blends (not shown here; see Ref. [12]), reveals quantitative upper limits on the length scale of mixing for the PIB/PEB-66 sample (single resonance in Figure 2c) at <70 nm. Consequently, all other PIB/PEB blends which exhibit two peaks in Figure 2 must be phase separated with average dimensions of the individual polymer-rich regions >70 nm. Armed with this length scale of mixing information, one can now use solid-state NMR methods to compare local chain dynamics at or near the glass-transition temperature for the PIB/PEB-66 blend vs. the other blend compositions, which are phase separated on the length scale defined by Figure 2 and the Xe PFG NMR data.

Two-Dimensional Exchange NMR to Probe Slow-Chain Reorientation

Figure 3 demonstrates the relationship between DSC measurements and 2D ^{13}C exchange NMR for pure PIB. This experiment, in addition to serving as the control experiment for comparisons to PIB/PEB blends, pedagogically illustrates the conformational dynamics associated with slow-chain reorientations at and above T_g. Figures 3 and 4 show the expanded region of the PIB CH_2 backbone carbon, which becomes sensitive to the distribution of conformer environments below ca. 235 K (see Ref. [10] for full spectral plots vs. temperature). The broad peak reflects the distribution of CH_2 groups for chain segments in trans–trans (tt), trans–gauche (tg), or gauche–gauche (gg) conformations along the polymer backbone. Little or no exchange is observed for a 1-s mix time (or less) at 203 or 208 K, as indicated by the lack of any off-diagonal intensity. However, for longer mixing times, exchange events are observed between the individual tt, tg, and gg peaks, as shown by the increased off-diagonal intensity at the 2- and 4-s mixing times. Examination of the ratio of an individual peak width perpendicular to the diagonal, vs. parallel to the diagonal, shows that conformer exchange is essentially complete after 4 s at 208 K (see Figure 3f). While the amount of conformational exchange is clearly reduced in Figure 3a–c vs. 3d–f, chain segment dynamics are observed at both temperatures for the 2- and 4-s mixing times.

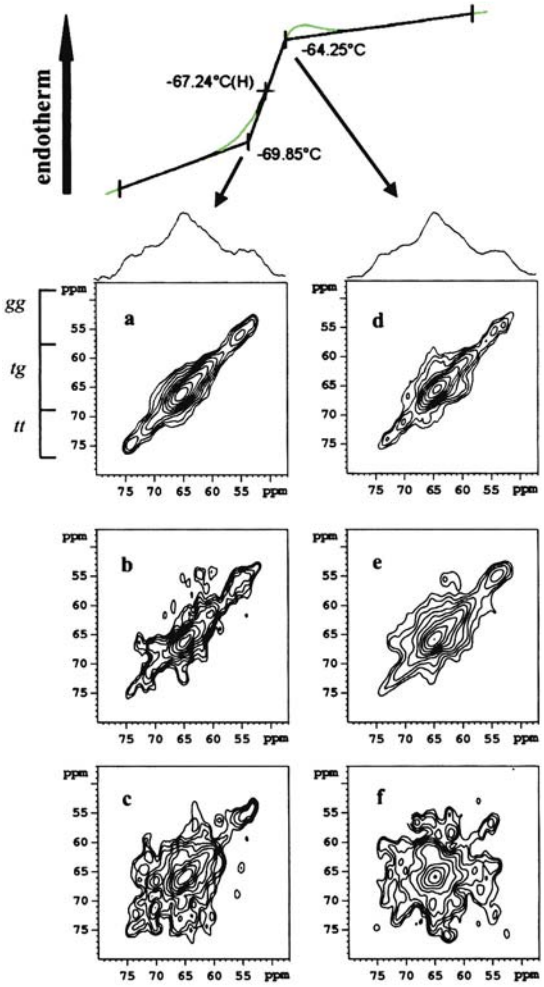

Fig. 3. Comparison of DSC T_g trace obtained with a 2 K/min scan rate (top) with 2D ^{13}C exchange spectra at (a) 203 K and 1-s mix time; (b) same as (A) at 2 s mix; (c) same as (a) at 4 s mix; (d) 208 K at 1-s mix time; (e) same as (d) at 2 s mix; and (f) same as (d) at 4 s mix. Spinning speeds were 4 kHz.

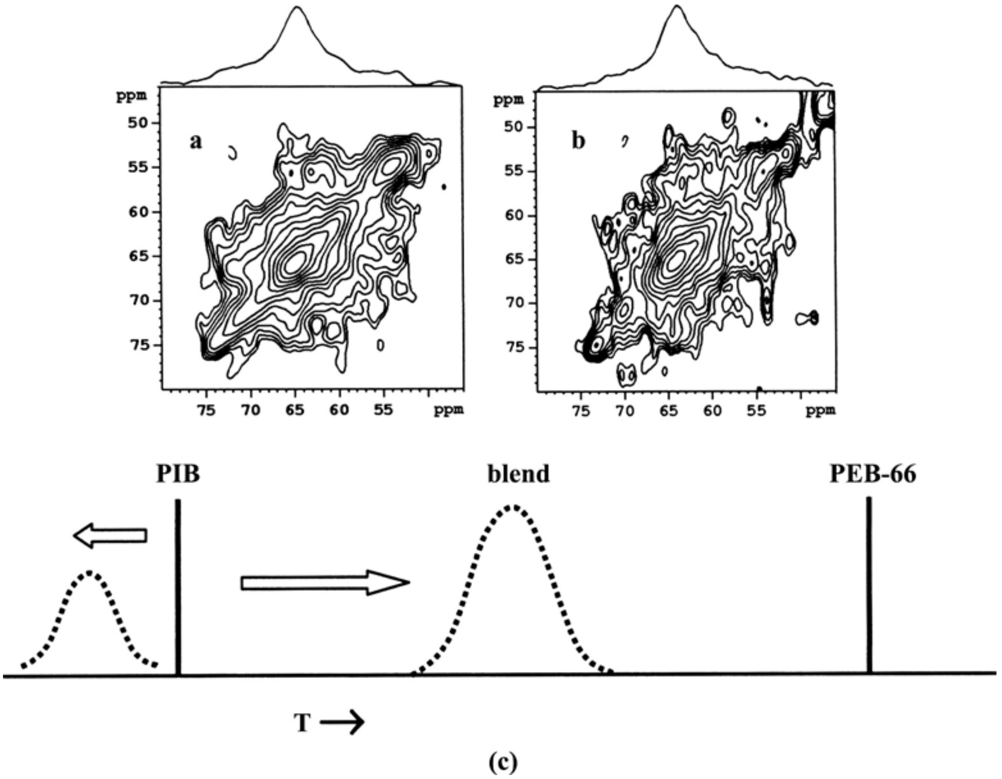

Fig. 4. 2D exchange spectrum at 208 K of (a) methylene carbons in pure PIB with a 2 s mixing time; (b) methylene carbons of PIB in a 50:50 blend with PEB using a 100 ms mixing time. Slices through the 65-ppm trans–gauche peak are shown on the top axis, and within the signal-to-noise limits, exhibit the same features; (c) Schematic diagram demonstrating differences in local (NMR, indicated by short gray arrow) vs. averaged (DSC, denoted by long gray arrow) T_g information for the blend components, and PIB in particular.

The site-specific dynamics revealed by the 2D exchange experiment can indicate changes in local glass-transition temperature/timescale upon formation of a miscible polymer blend. Figure 4a and 4b show results obtained at 208 K for a pure PIB sample and a 50:50 wt% blend of PIB and PEB, respectively. The PEB contained 66 wt% 1-butene units randomly incorporated into the chain; the sample in Figure 4b is the same PIB/PEB-66 blend sample used in Figure 2c. The 2D exchange patterns appear almost identical in terms of their off-diagonal intensity distribution, as confirmed by taking a slice through the tg peak at 63 ppm in each. This slice is shown as the top trace on each contour plot. However, while the PIB exchange pattern required a 2-s mixing time to achieve the off-diagonal signal in Figure 4a, the PIB/PEB-66 blend pattern in Figure 4b was obtained after *only 100 ms*. Additional experiments (not shown) for PIB blended with PEB-23 did not show this dramatic decrease in exchange time; the PIB/PEB-66 blend 2D exchange results were essentially identical to those of pure PIB in that several seconds were required to achieve measurable off-diagonal intensities. A major question in the study of polyolefin blend miscibility is the identification of the thermodynamic driving force for mixing, and in this case, PIB/PEB blends have been shown to be miscible for the PEB-66 composition used here [7–10]. The results of Figures 3 and 4 suggest that the rate of conformational dynamics of the PIB chains in the blend with PEB-66 are enhanced, or stated differently, the PIB "local T_g" is depressed in this blend, but not for other PEB compositions.

At this point, some key pieces of information should be provided for clarification. Firstly, the T_g's as measured by DSC for pure PIB and PEB-66 are −68 and −52 °C, respectively. By DSC, the PIB/PEB-66 blend has a broad, weak transition at −60 °C. Therefore, it is surprising that the conformational dynamics of PIB chains in the blend with the higher T_g PEB are enhanced, instead of being retarded. Secondly, the PEB-66 polymer also exhibits a conformationally sensitive signal in the ^{13}C NMR spectrum (see Ref. [10]); the CH_3 signal from the ethyl branch in PEB splits into inequivalent peaks at temperatures below ca. 235 K. In marked contrast to the PIB CH_2 backbone signal, no changes in the temperature dependence of the line shape were observed for the PEB-66 CH_3 peaks upon blending, nor were any differences in the low-temperature 2D exchange spectra observed for conformational dynamics involving this side group detected in control experiments comparing pure PEB-66 with PEB-66 in the PIB blend. In other words, while the PIB chain dynamics were markedly accelerated in forming the blend with PEB-66, no detectable perturbation of the PEB dynamics was observed in the frequency range 0.25–1 Hz (2D exchange) or in the range 500–1000 Hz [^{13}C one-dimension (1D) line shape analysis]. Moreover, it is unlikely that the PEB-66 dynamics are actually depressed upon blend formation, i.e. this polymer does not become more rigid when blended with the lower-T_g PIB. Figure 4c schematically represents the difference in local (NMR) vs. bulk (DSC) data.

The reduced exchange time (a kinetic quantity) of the PIB chains in the PIB/PEB blend (from Figure 4) may be related to the increased configurational entropy S_c (a thermodynamic quantity) using Adams–Gibbs theory [24,25], one form of which is shown below:

$$\tau_{ex} = \tau_0 \exp(c/TS_c)$$

Here, τ_{ex} is the exchange time for the redistribution of a single conformer's magnetization among all possible conformers, as measured by the 2D slices shown in Figure 4. This exchange time is analogs to a structural relaxation time, and represents the extent of conformational relaxation along the chain. Using the data from Figure 4, in which $\tau_{ex} = 2$ s and 100 ms for pure PIB and PIB in the PIB/PEB blend, respectively, we can solve for the *configurational entropy ratio* $S_{Blend}{:}S_{Pure}$. In this way, the constants τ_0 and c, and the temperature T, cancel from the equation. The resulting $S_{Blend}{:}S_{Pure} \geq 3.33$, indicating that the PIB chains in the blend with PEB have a much larger configurational entropy, and therefore, more accessible conformations per unit time, than pure PIB. Similar results were obtained by comparing equivalent 2D slices for PIB and PIB/PEB at 4- and 1.5-s mix times, respectively, at the same temperature as Figure 4. While this data are not shown for brevity, a similar $S_{Blend}{:}S_{Pure} \geq 3.4$ result was obtained. In fact, no matter which mixing time we choose from several different experiments, this ratio always exceeds three. These results suggest that entropy drives miscibility in this particular polyolefin blend, and the ability to place quantitative limits on key thermodynamic parameters should prove critical to a complete understanding of the heretofore-anomalous results in the area of polyolefin miscibility. Further, Adams–Gibbs theory requires that this increased entropy in the blend corresponds to smaller-sized cooperatively rearranging regions at a given temperature, i.e. a shorter T_g length scale [26]. Local motions become dominant in this regime, and the 2D exchange is clearly sensitive to these subtle changes. An alternative experimental strategy is to match the necessary equivalent 2D exchange patterns vs. T, thereby obtaining thermally activated configurational entropy changes in any amorphous polymer for which conformationally inequivalent signals are present.

^{2}H NMR Data and Simulations

The 2D ^{13}C exchange data shown in Figures 3 and 4 are only a small sampling of the total data collected.

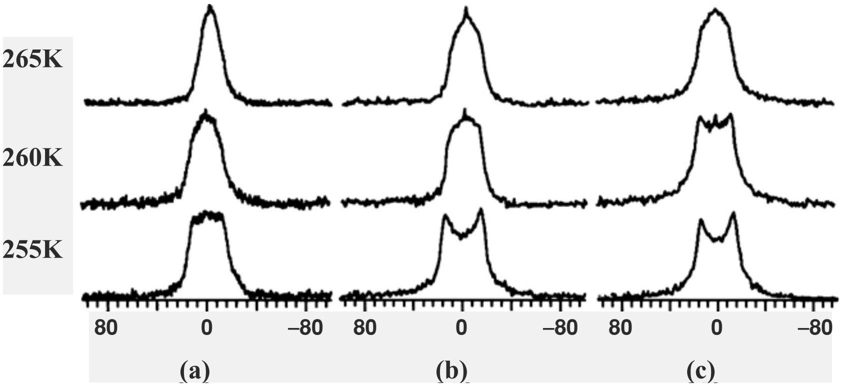

Fig. 5. Comparison of static ^{2}H NMR spectra over the NMR T_g range for 20%-PIB-d_8 chains in (a) a blend with PEB-66; (b) a blend with PEB-23; and (c) bulk, i.e. pure 20%-PIB-d_8. Note the difference in the spectral coalescence points in both (a) and (b), relative to (c), which is even more clear by comparing the line shapes across the second row.

Unfortunately, natural abundance exchange experiments are time consuming (10–20 h), which can be problematic for low-temperature MAS data collection. For the PIB/PEB blends, the 2D exchange data are consistent with both 1D line shape analyses and the Xe NMR data. However, static ^{2}H NMR is attractive as it allows site-specific information, and line shape simulation is straightforward. While the conclusions from the 2D data are undeniable, additional confirmation of the results using static ^{2}H techniques for the PIB/PEB system is useful. To this end, ^{2}H NMR data ***were obtained for pure PIB and its blends with PIB-23 and PEB-66 over the temperature range 210–298 K. Isotope effects on phase separation are known to occur for polyolefin blends. We avoid this possibility by using PIB containing only 15–20% of perdeuterated monomer for making the blends. According to our results from the Xe and 2D ^{13}C data, we should expect the largest perturbation in the temperature dependent ^{2}H line shapes for PIB in the PEB-66 blend. A small subset of the total data, shown in Figure 5, confirms this expectation. Figure 5 illustrates the unique line shape coalescence point for the three samples vs. temperature. The pure 20%-PIB-d_8 sample coalesces at 265 K (Figure 5c), while PIB/PEB-66 (Figure 5a) and PIB/PEB-23 (Figure 5b) coalesce at 255 and 260 K, respectively. The variations in CD_3 line shape for the PIB chains in the respective samples reflect the different frequencies of PIB chain reorientation in each environment. The Pake pattern for the PIB/PEB-66 blend exhibits an NMR glass transition at 255 K while PIB/PEB-23 blend does so at 260 K. Clearly, the PIB chain motional frequencies are perturbed more in the PIB/PEB-66 blend (containing 49 mol% butene) than in the PIB/PEB-23 blend (containing 13% butene). Further inspection of the line width and line shape at 265 K, the pure 20%-PIB-d_8 coalescence temperature, indicates that the PIB/PEB-66 line shape is already much more averaged than that of PIB/PEB-23. Clearly, PIB chains in both blends exhibit increased conformational mobility relative to the bulk PIB, as a result changing the particular line shape coalescence points of PIB/PEB-23 and PIB/PEB-66 by -5° and -8°, respectively. We were particularly surprised to see the -5 K shift for the PIB/PEB-23 blend, since the DSC thermogram shows two distinct, well-resolved T_g's (not shown).

Line shape simulations for the three samples, over the entire temperature range, were obtained using Weblab [27], and employing a four-site jump model. Excellent agreement was obtained, particularly around the line shape coalescence points shown in Figure 5 [12]. The Arrhenius plot shown in Figure 6 was constructed from these simulations of the conformational jump model. All three samples (PIB, PIB/PEB-66, and PIB/PEB-23) were accurately simulated using the four-jump model, which demonstrates that the PIB chain dynamics are the same in all samples. The only difference is that the motional frequency is increased at any temperature in the blends relative to the pure 20%-PIB-d_8. As mentioned before, the conformational dynamics of PIB are perturbed in the PIB/PEB-66 blend more than those in PIB/PEB-23, or in other words, the effective NMR T_g is reduced further. Figure 6a shows the reorientation rate obtained from the four-site jump model as a function of temperature for the pure 20%-PIB-d_8, 20%-PIB-d_8/PEB-23, and 20%-PIB-d_8/PEB-66. The slopes of the three systems indicate an isomerization activation energy equal to 36 kJ/mol. Additonally, the graph signifies intermediate

(b)

Fig. 6. (a) Arrhenius plot of chain reorientation rates obtained via simulation of the experimental static ^{2}H line shapes using the four-site model described in the text for 20%-PIB-d_8 chains in each of the indicated environments. The dotted lines indicate the region near line shape collapse. (b) Relaxation rate data vs. temperature for ^{2}H T_2 experiments. Note that the same activation energy is obtained via line shape simulation (a) and in the linear region of the T_2 curve (b).

behavior for the PIB/PEB-23 blend relative to the pure 20%-PIB-d_8 and the PIB/PEB-66. The activation energy obtained from the line shape simulations can be compared with the model-free relaxation experiments, e.g. T_2^{QE} as a function of temperature. From the graph in Figure 6b, the right and upward shift in the T_2^{QE} upon blending PIB with PEB-66 is evident, at the same time also revealing an activation energy equal to 37.5 kJ/mol. The direct link between the simulated and experimental data are clearly demonstrated by the matching activation energies acquired by two different methods, one of which is independent of any assumptions or physical jump model.

Conclusions

We have used a multifaceted experimental solid-state NMR approach to reveal that configurational entropy contributes to mixing in weakly interacting polyolefin blends composed of PIB and PEB. Many different independent NMR experiments provide a consistent picture of enhanced chain dynamics for the higher density, lower T_g PIB when it was blended with the higher T_g PEB-66. Additional blend systems are currently being investigated using higher chemical shift resolution exchange experiments, such as the recently reported CODEX technique [28]. While the PIB/PEB blends were easily interrogated with 2D exchange due the well-resolved PIB CH_2 signal, other polyolefin blends, e.g. PP/PE blends, often have too much signal overlap to use the 2D exchange method. PIB is unique due to its high chain packing density; it is not altogether unexpected that configurational entropy is important in its blend formation with other polyolefins. Clearly, we have shown that its miscibility with PEB-66 is not due to increased van der Waals forces resulting from increasing monomeric packing in three dimensions. However, until we obtain data on a wide series of structurally unique polyolefin pairs not just those involving PIB as one component, the general applicability of this concept to all polyolefin blends is still an open question. To this end, we have used similar solid-state NMR techniques, and others, to recently demonstrate that configurational entropy increases in the blend of head-to-head polypropylene (hhPP) with PIB relative to the unmixed pure polymers [29].

Introduction

The fast development and miniaturization of current computers will be slowing down probably after only a few decades. Current technology of the computers, hence so called classical computers, has been based on classical physics which fails if the size of the computers becomes as small as microscopic scales such as atomic or molecular entities.

A quantum computer is the introduced candidate for the future generation of the computers, which is based on the theory of quantum physics and then is properly well applicable to very small size of the computational elements [1]. In the classical computers, the computation and the information processing can be carried on the fundamental concepts so called bits. On the other hand, quantum computers are built upon quantum bits or qubits, by which the computation and the processing are governed in quantum mechanical nature [2].

As a result of the theoretical background difference between the two classes of the computers, classical and quantum, it is highly expected that some problems which are intractable for classical computers can be solved efficiently by quantum computers. For example, with the same input and output, a quantum processing of given information data represents exponential speed-up for factoring by Shor algorithm [3] and quadratic speed-up for search problems using Grover algorithm [4]. Also, by implementation of the quantum information algorithms such as quantum teleportation [5] and quantum superdense coding (SDC) [6], some intrinsic advantages can be achieved compared with the classical information processing. From the theoretical side, quantum information processing (QIP) and quantum computation (QC) have been established considerably well during the last decade [2]. Nevertheless, to build quantum computers as physical systems is still a big challenge. This is also true in terms of materials challenge. Realization of QIP and QC should involve qubits in microscopic scales. Computational tasks need manipulation of the qubits, whereas some interference among the quantum systems spoil the qubit systems and hence QIP and QC seem to be formidable tasks.

There have been considerable efforts to make quantum computers. According to the current technology, it seems that there is a long way to achieve a novel physical system which can present a quantum computer with all the promised advantages. Several physical systems, however, have been introduced as candidates for realization of QIP and QC [7–10].

A very well-known physical system for realization of a quantum computer is based on the nuclear magnetic resonance spectroscopy [7–8]. In this scheme, the quantum information is stored in nuclear spins, as qubits, of molecules. Liquid-state NMR spectroscopy has been widely used for implementations of even considerably complicated quantum non-local algorithms and the experimental outcomes apparently represent the capability of NMR as the physical system for QIP and QC [11–15].

Nevertheless, liquid-state NMR at room temperature suffers from its intrinsic low spin polarization, making the initial state in a highly mixed state, whereas the accessibility to a pure initial state is one of the major requirements for any physical system to be a valid candidate for the demonstration of a quantum computer [16], as is discussed later. In order to overcome this drawback, in a conventional approach, pseudo-pure states have been introduced [17–18] and widely used for NMR-based QIP and QC experiments.

Pseudo-Pure States and Quantum Entanglements

A pseudo-pure state is composed of two terms, the one belonging to the highly mixed state of the unitary part and the pure state term with a coefficient, which is related to experimental conditions. Referred to the current technology of the NMR spectroscopy at ambient temperature the corresponding value is as small as to typically 10^{-5}. Since all the observables in NMR are traceless the mixed

Graham A. Webb (ed.), Modern Magnetic Resonance, 647–654.
© 2008 *Springer.*

state term cannot be detected trough the NMR processing. Weak signal intensities, however, through the other term still give some information through quantum processing and then the whole pseudo-pure state looks as if an initial pure state has been used for the QIP.

Quantum entanglement is known as a prerequisite condition for any quantum non-local algorithm [19,20]. Thermal mixed states that have been used for NMR have been proved to be separable [21,22], therefore useless for the quantum non-local processing. Pseudo-pure states which apparently resolve the problem of the admixture of the initial state is not useful any more referred to the separability of the state, since the pseudo-pure state can also be represented as a convex combination of thermal states. The entanglement is a convex function. Then, the pseudo-pure states are at least as separable as the thermal states. In this context, liquid-state NMR with low spin polarization cannot afford entanglement-based advantages of QIP and QC. In order to solve this drawback, nuclear spin polarization should be increased to the extent expected by the theoretical criteria for the existence of entanglement. The enhancement of the nuclear spin polarization has been one of the recent focuses in the research field [23,24].

Despite the drawbacks of NMR as discussed, it is no doubt that NMR spectroscopy can be such a physical system as represents very important advantages for realization of quantum computers in some crucial aspects. The existence of nuclear spins with long decoherence time is proper physical realization of a qubit since the spin manipulation can easily be performed by introducing radio frequency pulses with relevant resonance frequencies. In this context, to retain the advantage of long decoherence times is crucial for looking for novel physical systems in which easy-to-access spin manipulations are performed. In this study, pulse-based Electron Nuclear DOuble Resonance (ENDOR) [25] has been examined as a novel candidate to approach a quantum computer by invoking molecular entities with both electron spins and nuclear spins in the solid state. Since the physical system under study involves nuclear spins, pulsed ENDOR spin-manipulation technology retains the main advantage inherent in QC NMR systems. In addition, it seems easier to overcome the drawbacks of the NMR systems for realization of quantum computers because additional molecular electron spins originating in open-shell electronic structures are also incorporated in the corresponding physical systems.

Nevertheless, an ENDOR based quantum computer as electron-nuclear multiple magnetic resonance spectroscopy is much heavier experimental task compared with NMR or electron paramagnetic (spin) resonance (EPR/ESR), but QC-ENDOR rewards back the much more efforts by adding up the advantages of NMR and EPR. It is worthwhile to notice that an elaborate total design of the QC-ENDOR experimental setup should be associated with molecular design for open-shell entities. Tuning relaxation times of molecular open-shell entities is crucially important in the QC-ENDOR setup.

Molecular ENDOR Based Quantum Computer

For any physical system as a candidate for the realization of a quantum computer, there are some fundamental criteria, known as DiVincenzo criteria that should be met [16]. The molecule-based ENDOR system is also expected to meet these criteria in order to be a realistic physical system for QIP and QC; see Table 1 for a list of DiVincenzo criteria and properties of the ENDOR system.

In the ENDOR-based QIP and QC, molecular electron spins in addition to nuclear spins have been introduced as quantum bits (qubits). In a thermal equilibrium, the populations in the ground states with molecular electron spins are more than 10^3 times larger than the corresponding excited states in the presence of a static magnetic field or the ones with zero-field splittings. Therefore, with ENDOR systems, achievement of the required experimental conditions for preparing the initial state for QIP and QC seems to be substantially easier with the current technology. The exact and complete preparation of the pure initial state, however, requires manipulation of single molecule systems, for which electron magnetic resonance or Larmor precession detection has been considered and even the experimental equipments seem to be accessible in the near future.

Any physical system for QIP and QC should be chemically stable during computational processing. We have prepared robust organic open-shell entities against long and high-power irradiations of radio frequency and microwave at ambient temperature, as one among those exemplified in this contribution. In addition, the corresponding decoherence time of the qubits is expected to be long enough compared with the computational or operational time. As a result of the existence of the nuclear spins in molecular open-shell entities, there is a wide possibility to work with samples with the long decoherence time. Proper samples with the long decoherence time and their synthetic procedure should be considered, in advance [26]. Long enough decoherence times for samples involving two qubits have been measured during the course of this work; for a particular molecular entity the feasibility of the ENDOR-based QIP and QC has been examined from both experimental and theoretical sides as is reported in the following sections.

In QC-ENDOR, manipulation and processing on the qubits as well as the readout processing can be realized by introducing both microwave and radio frequency pulses in an approach different from NMR QC experiments, i.e. ENDOR pulses, on the nuclear spins or by the microwave frequency pulses on the electron spins (see Figure 1).

Table 1: ENDOR systems regarding the satisfactions of the DiVincenzo criteria

	DiVincenzo criteria	ENDOR
Qubit	Identifiable, well characterized qubits are required.	Molecule-based electrons and nuclear spins in molecular open-shell entities based on chemical syntheses and identifications.
Initialization	Possibility to be initialized to a simple and fiduciary state.	Pseudo-pure states might be used in this context, whereas in case of avoiding pseudo-pure states, it is proposed that high polarizations of the electron spin can be coherently transferred to the nuclear spin by applying relevant pulse sequences followed by proper waiting times.
Decoherence time	Long relevant decoherence times, much longer than the gate operation time is necessary.	Long decoherence times of the nuclear spins and electron spin have been available for the demonstration of quantum operation between the two spins. Proper molecular entities with long decoherence times for multi-qubit operations are not out of reach, for which stable isotope-labeled open-shell molecules have been designed and synthesized [26].
Quantum operation	Universal set of quantum gates is required.	Quantum gates between a single electron and a single nuclear spin have been demonstrated in an experimental task. Multi-qubit operations in terms of ENDOR spin Hamiltonians are underway.
Measurement	The ability of measurements on the quantum qubits to obtain the result of the computation is required.	The current measurement scheme is an ensemble one. However, single electron spin detections may be available in the future by the use of STM-based electron magnetic resonance detection.

It is known that the realization of particular quantum gates being known as universal gates can be enough for implementation of any other quantum gates [2]. One-qubit gates in addition to a non-trivial two-qubit gate, e.g. Controlled-NOT gate (CNOT), give a universal set of quantum gates. For implementations of quantum gates, it is possible to perform this task by introducing the relevant pulses. From the experimental side, for the QC-ENDOR system particular quantum gates have been demonstrated by means of the two qubits, as it is described in the following section. Multi-qubit gates for molecular systems involving larger number of qubits should be considered for the relevant physical system in terms of the particular form of the spin Hamiltonian for the corresponding sample. There are several typical types of the quantum operations based on multi-qubit-gates, depending upon spin Hamiltonians for realistic QC-ENDOR experiments [26].

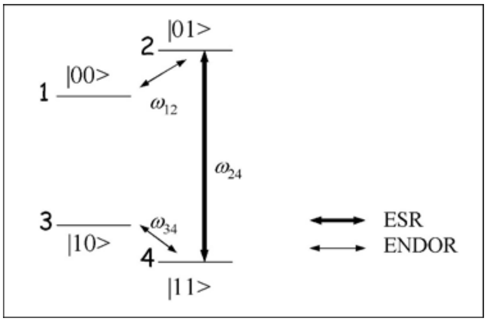

Fig. 1. Energy levels and corresponding EPR/ESR and ENDOR resonance transitions in the presence of a static magnetic field. Note that the nuclear sublevels correspond to the case for the system with a positive hyperfine coupling. The definition for the level is as follows; $|00\rangle$ and $|10\rangle$ denote $|Ms = +1/2, M_I = +1/2\rangle$ and $|Ms = -1/2, M_I = +1/2\rangle$, respectively. Similarly, $|01\rangle$ and $|11\rangle$ denote $|Ms = +1/2, M_I = -1/2\rangle$ and $|Ms = -1/2, M_I = -1/2\rangle$, respectively. Also, see the text for the use of the notation of the sublevels.

In the ENDOR based QC, the readout or the measurements have been implemented by introducing the radio frequency and Microwave pulses on nuclear spins and electron spins, respectively. Nevertheless, as is in a similar approach to the NMR QC, the measurement scheme is an ensemble measurement and rather different from the exact measurement which is required for QC. In terms of QC-ENDOR, to solve this problem is still an open problem. As has been already mentioned, the QIP and QC have been changed in a manner which the results through the ensemble measurements can give the required information. However, in the ENDOR based QC, we have been only proposing the single molecule system for which the measurements can be accomplished by single electron spin detection as discussed above.

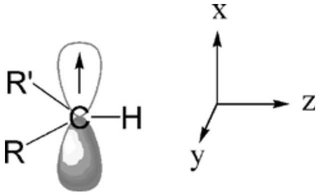
It has been proved that for the case of pure states entanglement is the necessary requirement for quantum exponential speed-up over the classical counterpart. For mixed states the statement has still not been proved, but highly believed to be correct. Therefore, one very important issue which should be examined for any physical system for QIP and QC is the entanglement status. Realization of the entanglement between an electron spin and a nuclear spin has been reported in an ENDOR experiment by using the pseudo-pure states [27].

We have been mainly engaged in two experimental tasks for the realization of a quantum computer by molecule-based ENDOR. One has been attempts for the preparation of the experimental requirements for demonstrating a true entanglement between a molecular electron spin and a nuclear spin by the use of a simple organic radical in the single crystal and avoiding the use of pseudo-pure states. High spin polarizations on both the electron and nuclear spins are essentially required to achieve the true entanglement between the two spins in the molecular frame. Investigation of the entanglement for the ENDOR system composed of only two electron and nuclear spins gives a necessary temperature of 0.8 K in a static magnetic field for the microwave transition frequency of 95 GHz, as given by the negativity criterion [28,29]. Whereas, if pulses can be applied for the transfer of the high spin polarization, the required temperature at the same magnetic field is nearly 5.1 K, which is well in reach with the current technology with a W-band (95 GHz) ENDOR spectrometer operating at liquid Helium temperature.

While the preparation of all the experimental requirements is in progress, the efforts still can be maintained on some other aspects of the research. The other is materials challenge to design and synthesize stable open-shell molecular entities suitable for QIP/QC ENDOR experiments. Novel molecular open-shell systems with stable isotope labels suitable for our purposes have also been designed and synthesized [26]. Also, the critical temperature can be tuned by invoking stable high-spin molecular entities.

Also, the efforts have been made on the investigation of the credibility of the pulsed ENDOR based QIP and QC to develop the necessary quantum gates and the entangling unitary operations. It is clear that in case of acquiring the former task with the achievement of the experimental conditions for establishing entanglement and also pure states, there would be no need to have an additional experimental processing to make the pseudo-pure state.

In order to check the credibility of the ENDOR physical system for QIP and QC and also to check the feasibility of the molecule-based QC-ENDOR with current technology, implementation of SDC [6] has been revisited in our experiments. Pulsed ENDOR technique has been applied to a molecular electron- and nuclear-spin system, i.e. malonyl radical in the single crystal of malonic acid [30], in order to implement the SDC.



Scheme 1. Generation of malonyl radical by X-ray irradiation.

Preparation of the Molecular Entity for QC-ENDOR

Malonyl radicals incorporated in the single crystal of malonic acid were generated by X-ray irradiation at ambient temperature as shown in Scheme 1. Spin Hamiltonian parameters of malonyl radical under study, as summarized in Table 2, have been reported by McConnell *et al.* [30]. A typical echo-detected field-swept ESR spectrum of malonyl radical observed at 20K is shown in Figure 2. Pulsed ENDOR measurements for malonyl radical were performed with a Davies-type pulse sequence [31] and an observed Davies-ENDOR spectrum is shown in Figure 3.

Existence of one α-proton with a large hyperfine coupling gives two spins as the required two qubits for SDC. The large hyperfine interaction is primarily required to enable us to make a selective microwave excitation. Energy

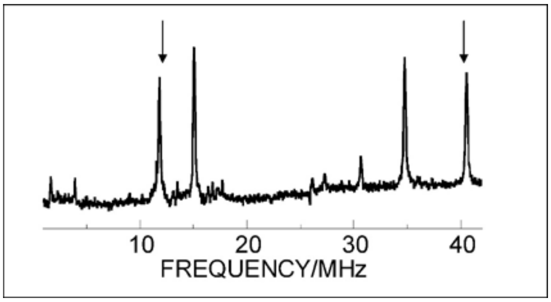

Fig. 3. Pulsed ENDOR spectrum from malonyl radical with the magnetic field set as in Figure 2. A selective MW pulse for the preparation and non-selective MW pulses for the detection were applied. The arrows indicate the ENDOR transitions due to α-proton (see Figure 2) of malonyl radical with a negative hyperfine coupling.

levels and the corresponding resonance frequencies of the radio and microwave frequencies are shown in Figure 1, noting that the order of the nuclear sublevels should be reverse for malonyl radical with the negative hyperfine coupling (see Table 2). Detection of the pseudo-entanglement with this system has been already reported [27] and in a different approach we demonstrate implementation of SDC by the use of pseudo-entangled states.

Implementation of SDC by Pulsed ENDOR

SDC introduced by Bennett and Wiesner [6] is a non-local quantum algorithm in which two classical bits of information have been transformed from Alice to Bob by sending only a single qubit. The scheme is based on the fact that the entangled initial states have been shared between the two involved parties. The efficiency of the scheme is two times compared with the classical counterpart, since maximum one bit of information can be transferred through a single use of an information channel.

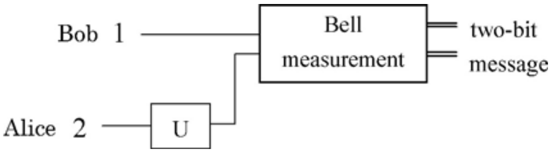

Fig. 4. Scheme for superdense coding. U denotes a unitary transformation.

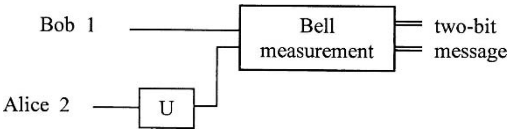
Simply SDC can be explained as follows (see Figure 4): Two qubits which are originally entangled with each other have been shared between two involved parties, say Alice and Bob. Alice encodes the qubit by applying a unitary transformation out of the four choices of $\{I, X, Y, Z\}$ and then sends the encoded qubit to Bob, who has been also initially given a qubit entangled to the Alices's one. After receiving the encoded qubit from Alice, Bob applies a measurement in the Bell basis (see Table 3) on the both of the qubits. The result of the measurement makes it clear for Bob that what the Alice's choice has been in the encoding part. Therefore, he extracts the information on the Alices's choice, which means a two-bit message has been transferred by sending only a single qubit.



Concepts for ENDOR-based experimental setup for two-qubit SDC are depicted in Figure 5, in which S and I denote the electron-spin part and nuclear spin one. Figure 5 shows one of quantum circuits implementing SDC. The quantum circuit for SDC consists of Hadamard and controlled NOT (CNOT) gates. U_i stands for one of the unitary transformation for encoding. The first Hadamard

Table 3: The unitary operation and corresponding pulse sequences for encoding

	Initial state	Necessary operation	Required pulses	Encoded state
$U = I$	$\frac{1}{\sqrt{2}}(\|00\rangle + \|11\rangle)$			$\frac{1}{\sqrt{2}}(\|00\rangle + \|11\rangle)$
$U = X$	$\frac{1}{\sqrt{2}}(\|00\rangle + \|11\rangle)$	$\exp(-i\pi I_x)$	$P_x^{34}(\pi)P_x^{12}(\pi)$	$\frac{1}{\sqrt{2}}(\|01\rangle + \|10\rangle)$
$U = Y$	$\frac{1}{\sqrt{2}}(\|00\rangle + \|11\rangle)$	$\exp(-i\pi I_y)$	$P_x^{34}(2\pi)P_x^{34}(\pi)P_x^{12}(\pi)$	$\frac{1}{\sqrt{2}}(\|01\rangle - \|10\rangle)$
$U = Z$	$\frac{1}{\sqrt{2}}(\|00\rangle + \|11\rangle)$	$\exp(-i\pi I_y)$	$P_x^{34}(2\pi)$	$\frac{1}{\sqrt{2}}(\|00\rangle - \|11\rangle)$

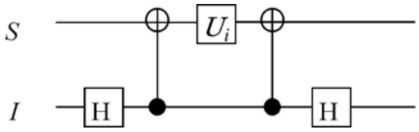


Fig. 5. Quantum circuit implementing SDC.

and CNOT gates generate an entangled state between the electron and nuclear spins. Following the unitary transformation, the CNOT and Hadamard gates back-transform the entangled state, being responsible for extracting the encoding results. Except for a phase factor which dose not affect any signal, selective $\pi/2$ and π pulses are available for the Hadamard gate for single qubit and the CNOT gate for two-qubit in pulsed magnetic resonance spectroscopy, respectively.

SDC has been implemented using some quantum physical systems including NMR [7]. This contribution gives a report on the implementation of the SDC by ENDOR. However, the main idea is only to test the ENDOR system for QIP rather than total implementation of SDC, giving a testing ground for QIP and QC to molecule-based ENDOR. As the latter, one has been argued to be truly realizable in case of manipulating the entangled state and not just by a pseudo-entanglement. In our experiment, states have been prepared as pseudo-pure ones in a similar approach as reported by Mehring's group [27].

The pulse sequence that has been used for implementation of SDC with our ENDOR experiments is represented in Figure 6. There are three main parts of the sequences, i.e. the preparation of the pseudo-pure states, manipulation and finally detection according to the customs in magnetic resonance spectroscopy.

The outermost left part labeled by "A" is for the preparation of the pseudo-pure state. Two pulses on electron and nuclear spins with additional waiting times in order to make the off diagonal term of the density matrix vanishing are required to acquire the pseudo-pure state. The first two pulses in the central part of the sequence are for entangling and also the last two pulses are for detection of the entanglement as reported by Mehring's group [27]. Two phases of Φ_1 and Φ_2 for the pulses in the detection part are required for clearing up the entangled states from the simple superposition states. In the central part between the entangling and detecting the entanglement, which is labeled by B2, one of the qubits, nuclear spin in our experiment, is encoded by randomly applying one of the four pulses of $\{I, X, Y, Z\}$. The necessary pulses for encoding are described in Table 3.

Finally, there are pulses for the detection by an electron spin echo signal. For the measurement part, the situation has been modified for some detection considerations. In this study, we have used the electron spin echo detection. The echo intensities have been detected for different angular dependencies of the pulses in the encoding part. As a result, there are four sets of angular dependencies for radio frequency pulses which have been used for encoding, (see Table 4).

In QC/QIP-ENDOR, unitary operations are realized by some particular pulse operations with controlled

Table 4: Detection through angular dependence of the intensities of the electron spin echo

	Angular dependent radiofrequency pulses for encoding	Detected angular dependent echo intensity
$U = I$		$\frac{1}{4}(-1 + \cos[\phi_1 - \phi_2])$
$U = X$	$\omega_x^{34}(\theta)\omega_x^{12}(\phi)$	$\frac{1}{16}\left(-3\cos\theta - \cos\phi + 4\cos\frac{\theta}{2}\cos\frac{\theta}{2}\cos[\phi_1 - \phi_2]\right)$
$U = Y$	$\omega_x^{34}(2\pi + \theta)\omega_x^{12}(\phi)$	$\frac{1}{16}\left(-3\cos\theta - \cos\phi - 4\cos\frac{\theta}{2}\cos\frac{\theta}{2}\cos[\phi_1 - \phi_2]\right)$
$U = Z$	$\omega_x^{34}(\theta)$	$\frac{1}{16}\left(-1 - 3\cos\theta + 4\cos\frac{\theta}{2}\cos[\phi_1 - \phi_2]\right)$

phases and polarizations. Phase manipulations are crucial in the molecule-based ENDOR experiments for QC and QIP. Table 4 shows the angular dependence of the electro-spin-echo intensities in the detection part, depending also on experimental conditions for the measurements. In the SDC experiments, the detected echo intensities incorporate the terms characteristic of 4π period, as shown in Table 4. We have detected this salient behavior of the intensities, exemplifying the case for $U_i = X$ as given in Figure 7. In contrast to the 2π period of the population, the observed 4π period originates from the spinor property [32] as the intrinsic nature of spins under study with the experimental condition of the selective microwave excitation. The sign difference appearing between Figure 7 and Table 4 is due to the difference between the experimental setup. The case for non-selective microwave excitations is under study.

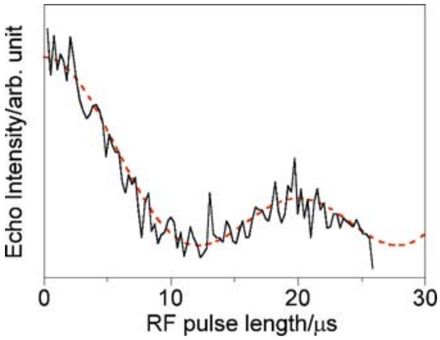

Fig. 7. 4π Period dependence of the electron spin echo detection scheme. Microwave frequency: $\nu = 9.38725$ GHz. Static magnetic field set for ENDOR: $B = 335.918$ mT. Temperature: $T = 20$ K.

Conclusion

We have introduced a pulsed ENDOR based approach to QIP and QC by invoking molecular electron and nuclear spins in the solid state. Pulse ENDOR technology retains the main advantages of NMR systems, and at the same times it seems relatively easier to overcome the difficulties that conventional NMR technology suffers from. We have noticed that time domain of electron spin manipulation technology is shortened and its present drawback is a matter of time resolution from the experimental side. In this research, it is aimed to demonstrate ENDOR-based QIP and QC by achieving the entangled states between a molecular electron spin and nuclear spins of a stable organic radical through high spin polarizations and also developing entangling unitary operations.

At first, our efforts have been made to develop entangling unitary operations in order to check the credibility of the molecule-based ENDOR QIP from both the theoretical and experimental sides. Angular dependent electron-spin echo intensities in the readout measurements have been derived in simple analytical expressions for SDC-ENDOR experiments. Thus, we have implemented SDC by acquiring the pseudo-pure states. The preliminary experimental results are well representing the feasibility of the ENDOR QIP. We have shown that phase manipulations of electron and nuclear spins in a controlled manner as well as the polarizations are crucial in QC/QIP ENDOR, demonstrating that the spinor nature of spins manifests itself in molecule-based pulsed ENDOR for SDC.

We are planning to examine the real QIP and QC by avoiding pseudo-pure states and introducing pure states in order to prepare the quantum entanglement between molecular electron spins and nuclear spins. It has been shown that in contrast to the conventional NMR systems, the experimental requirements for achievement of spins with high polarization are not far beyond the current ENDOR spin-manipulation technology. Also, currently, weakly electron-exchanged coupled systems composed of molecular open-shell entities have been designed, as materials challenge, based on bio-inspired molecular magnet approaches and the synthetic procedures are underway. This materials challenge is for implementation of molecule-based pulsed electron–electron and electron–nuclear magnetic resonance spectroscopy for QC and QIP.

Residual Dipolar Couplings and Nucleic Acids

New Applications for Residual Dipolar Couplings: Extending the Range of NMR in Structural Biology

Rebecca S. Lipsitz and Nico Tjandra
Laboratory of Biophysical Chemistry, National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, MD 20892, USA

Background

Less than 10 years since their introduction, residual dipolar couplings (RDCs) have become a mainstay in Nuclear Magnetic Resonance (NMR) methodology [1–4]. Dipolar couplings are anisotropic through-space interactions between magnetic nuclei. In solution samples, Brownian motion causes all orientations to be sampled with the same probability; there is no net anisotropic orientation needed in order for the dipolar coupling to be observed. However, there have been recent advances where the presence of various types of solution media imparts a small degree of anisotropy, a RDC [5,6]. Under these conditions, the molecule retains isotropic properties such as rapid tumbling and narrow line widths.

RDC data are complementary to NOE data; whereas NOEs provide distance information between atoms less than 5 or 6 Å, RDC data allows the relative orientation of bond vectors to be determined, regardless of their actual translational proximity within the molecule. RDCs have been a boon for NMR research and have allowed exploration into research areas heretofore unexamined such as relative orientation of protein domains/protein complexes, global structure of oligonucleotides, structural propensity of unfolded proteins, prediction of protein folds, and information on glycosidic angles in carbohydrates. In this review we highlight some of the most interesting applications within the past few years.

Theory

The RDC, D_{AB} can be expressed as follows

$$D_{\mathrm{AB}}(\theta,\phi) = \frac{S\gamma_{\mathrm{A}}\gamma_{\mathrm{B}}}{r_{\mathrm{AB}}^3}\{A_{\mathrm{a}}(3\cos^2\theta - 1)\} + \frac{3}{2}A_{\mathrm{r}}(\sin^2\theta\cos 2\phi) \qquad (1)$$

where A and B refer to the interacting nuclei, A_{a} is the axial component of the molecular alignment tensor $\mathbf{A}$, A_{r} is the rhombic component of $\mathbf{A}$, θ and ϕ are the polar angles describing the angle the inter-atom vector makes with the alignment tensor, S is the order parameter, γ is the gyromagnetic ratio, and r_{AB} is the internuclear distance. The advantage of using RDCs for nuclei of known bond lengths is that the only variables in Equation 1 are θ, ϕ, and S. It is routine to assume that S is constant throughout the protein or to omit data for nuclei where relaxation data indicates high-amplitude motion.

Knowing the value of the principal components of $\mathbf{A}$ is a pre-requisite for using the RDC data in structure calculations. There are various methods to determine these values such as singular value decomposition (which requires a starting structure for fitting the RDC data and a minimum of five measured RDCs) [7], histogram analysis of the measured RDCs (which requires sufficient geometric sampling of the data) [8], and grid search approaches [9]. In many cases there are inherent limitations that make it difficult to measure a large number of RDCs. Using the known covalent geometry of the peptide plane it is possible to increase the amount of data with computer-generated RDCs [10]. Programs such as PALES [11] can be used to compute the alignment tensor values.

In experimental data, the RDC is observed as an addition or subtraction (RDCs can be positive or negative) to the scalar J coupling. In order to extract the RDC values it is necessary to measure the apparent J coupling under both isotropic and anisotropic conditions [1,12–15].

There are a considerable number of media used to align samples based on different mechanisms of alignment, i.e. steric obstruction vs. electrostatic interactions. However, sample preparation is a delicate art and it is difficult to predict which media will satisfy the requirements that the sample does not interact with the media and that the sample does not become degraded. Some of the most commonly used alignment media include bicelles, phage particles, purple membranes, poly-γ-benzyl-L-glutamate (PBLG) strained polyacrylamide gels, etc. [16–24].

One of the first applications of RDC data was for protein structure refinement. Modules have been added to XPLOR-NIH expressly for this purpose [25]. A target function is employed which uses a force constant based on the uncertainty of the measured data. An *OXYZ* pseudoatom which represents the coordinates of the alignment

Graham A. Webb (ed.), Modern Magnetic Resonance, 657–664.
© 2008 *Springer.*

tensor is incorporated into the atomic coordinates and allowed to rotate freely during the refinement [26,27]. Molecules refined with RDC data show noticeably improved RMSDs which helps to delineate important functional features of the molecule.

Protein Structures

In cases where there is a paucity of NOE data, RDCs have substantial impact on the structural precision. Two such examples are the structure of *Thermotoga maritime* cold shock protein solved at 343 K, a temperature at which RDCs were necessary because many NOEs were no longer observed or had diminished signal to noise [28]. Completion of this structure allowed for comparisons with a structure of the same protein solved at room temperature. For high molecular weight proteins spectral overlap makes it difficult to assign all the resonances. One approach in this situation is to use selective labeling in order to simplify the spectra. This results in a non-uniform NOE distribution and RDCs can help to compensate for the low number of long-range distance restraints. The 723-residue protein malate synthase G is an example of a protein whose fold could not have been determined without using RDCs. This work demonstrates the feasibility of determining the structures of high-molecular weight protein by NMR [29].

In multi-domain proteins it is difficult to determine the relative orientations of domains within a protein without RDCs because they are usually too far apart for inter-domain NOEs to be detected. However, assuming that the linker in between the domains is not flexible the relative domain orientation can be determined by calculating the alignment tensor for each domain and then rotating the domains until their alignment tensors coincide. Subsequently, rigid-body dynamics is commonly used to determine the final structure [30,31]. Examples of structures of multi-domain proteins determined this way include barley lectin [32] T4 lysozyme [33]. RDCs were used to solve the structure of the p47^{phox} dimer and to show that the two tandem SH3 domains are arranged in a compact, globular manner, similar to what was observed in the crystal structure [34].

RDCs can be used to understand how a solution structure solved by NMR differs from the corresponding crystal structure or ways in which a protein changes conformation in response to ligand binding. Kay and coworkers, have performed a series of studies on the 370-residue maltose-binding protein both with and without ligands. The apo "open" form is very similar to its crystal structure counterpart. In the case of one particular ligand, β-cyclodextrin, there was a disagreement between the solution structure and the crystal structure in that the solution conformation the two domains were 10° closer to each other in than in the crystal structure [35,36]. In order to monitor the change in conformation from open to closed, Millet *et al.* have performed RDC studies on various mutants in the domain linker region that force the domains to move into an increasingly more closed conformation, showing the structural transformation as the protein moves from the open to closed forms [37].

There are some cases where RDCs have helped to establish the existence of deviations in relative domain orientation between similar structures solved by x-ray crystallography and NMR. Zhang *et al.* showed that the nucleotide-binding domain of Hsc70, which contains four domains, has a relative domain orientation that differs from 14 previously solved crystal structures. Differences in the alignment tensor of the 4 domains suggests that inter-domain flexibility may be viewed as a mechanism for "modulating" inter-domain interactions as well as interactions with cofactors [38].

Hemoglobin is an example demonstrating the use of RDCs to determine a novel solution conformation. In this case, discrepancies between measured RDCs and RDCs calculated from crystal structures of two allosteric forms of the protein suggested that the conformation of the solution sample did not match either of two previously characterized allosteric states. In order to determine the orientation of the solution conformation, the relative orientation of the domains was systematically adjusted until the calculated RDCs coincided with the measured RDCs. It was found that the orientation in solution lies in between the two allosteric conformations [39]. Figure 1 depicts the three different conformations.

DNA/RNA

DNA

Traditionally, the global features of nucleic acid structure have been challenging to assess. Use of RDCs has shown that crystal structures and NMR structures using only NOEs, J couplings, and torsion angle restraints leads to imprecise or inaccurate structural representations. RDCs not only greatly improve structural convergence within a family but in so doing allow global parameters to be determined such as DNA curvature. For example it has been shown that inclusion of RDC restraints into the structure of a DNA dodecamer causes the range of curvature values within a family of structures to be significantly decreased [40]. Without RDCs, the number of long-range structural restraints is limited due to low chemical shift dispersion, low proton density (as compared to proteins) and the near-absence of long-range NOEs. Inclusion of RDCs improves the local geometry and subsequently the global geometry. In fact several authors have highlighted the interplay between local and global geometry emphasizing

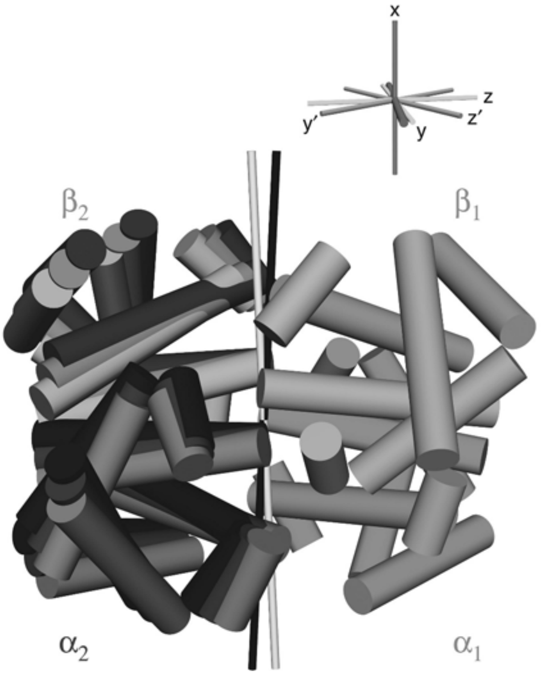

Fig. 1. Schematic illustration of the R and R2 crystal structures, together with the solution conformation, of hemoglobin. Helices are shown as cylinders. Here, the $\alpha_1\beta_1$ dimers of the two structures have been superimposed and are indistinguishable. The α_2- and β_2-subunits of the R, solution, and R2 structures are shown in dark, medium, and light shades, respectively, of red and blue. The C2 symmetry axes of the R and R2 structures are shown as thin black and white rods, respectively. (*Inset*) Alignment frames of the best-fit solution structure in bicelles (x, y, z) and Pf1 phage (x, y, z), where the x and x axes coincide with the C2 axis. The R→R2 rotation axis is shown in orange. Reprinted with permission from ref. [39]. (See also Plate 61 on page XLIII in the Color Plate Section.)

that inaccuracies at the local level tend to propagate throughout the molecule leading to inaccuracies in global geometry. Only a handful of RDCs are needed to have a dramatic effect on the structure [41]. However, to overcome the paucity of ^{1}H–X measurable internuclear RDCs in nucleic acids, methods have been developed to measure interproton ^{1}H–^{1}H RDCs up to 12Å apart [15,42,43].

A number of RDC studies on DNA molecules have focused on A-tracts, series of 4 or more adjacent A-T base pairs which induce unusual curvature that may have a functional role in transcription [44–46]. Crystal structures of A-tracts do not exhibit this curvature, most likely due to lattice packing effects, and therefore show discrepancies when compared to the corresponding solution structure. NMR structures of A-tracts show great variability in the DNA curvature. Since RDCs are particularly helpful for assessing parameters such as DNA curvature, studies by Steft, Barbic, and Lu have helped to end a longstanding debate over the type of model (wedge or junction) that best describes A-tract curvature. The consistent results within these RDC studies supports a modified version of the two models, referred to as the "delocalized bend model."

Use of RDCs makes it possible to quantify geometric properties that both define and distinguish DNA such as base pair roll, tilt, and twist angles. These values can be used to better understand the relationship between nucleotide sequence and structural irregularities in DNA that serves a functional purpose. As an example, Wu *et al.* have built on previous RDC studies of the DNA Dickerson dodecamer using an extremely large number of RDCs including both heteronuclear and homonuclear RDCs as well as ^{31}P CSA values [47,48]. Unlike previous crystal structures which show irregular features including abnormal backbone torsion angles, the structure using RDCs demonstrates that the Dickerson dodecamer is highly regular.

RNA

Structure determination of RNA molecules is complicated by the fact that RNA suffers from many of the same drawbacks and limitations as DNA but with additional challenges such as intricate secondary structure, mobility between different RNA segments, non-uniform alignment tensors, etc [49,50]. RDCs can aid in characterizing unusual, but functionally important geometry that arises from bulges, mismatches, and loops. Pardi and co-workers have demonstrated how to use RDCs in a number of different RNA structure calculations. The structure and relative orientation of the two helical arms of the tRNA$^{\mathrm{Val}}$ was determined by using measured RDCs with the known structure of similar tRNA as a template. Detailed discussions about important considerations for implementing RDC in structure calculations are included in this work and others [51–53]. Reiter *et al.* have used RDCs to investigate pH-induced conformational changes as a result of a base flip which shifts the positions of the upper and lower helices in the U6 RNA stem-loop [54].

RDCs have been used in studies investigating the effect of Mg^{2+} binding on the conformation and dynamics of RNA molecules. In the case of the HIV-1 TAR RNA molecule it was shown that in the free form its two stems have an average inter-helical angle of 47° which both exhibit significant mobility, and thus have different alignment tensors [55]. Addition of Mg^{2+} leads to a rigidification of the molecule; all RDC values are scaled in a manner which indicates that both stems behave as a single entity and the inter-helical angle is reduced to 12° [56].

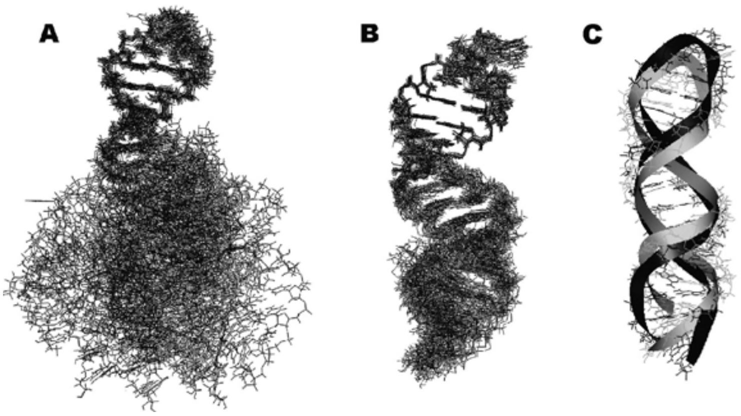

Fig. 2. NMR structures of the consensus stem-loop D RNA. (A) The 25 lowest energy structures refined with the conventional distance and torsion angle restraints. (B) The same structures calculated with the inclusion of 136 ^1H–^{13}C one bond RDC restraints. (C) Superposition of the average structures calculated with (gray) or without (black) RDCs. Further details may be found in the original publication. Reprinted with permission from ref. [41].

The solution structure of the hammerhead ribozyme without Mg^{2+} was compared to the crystal structure of the hammerhead ribozyme with Mg^{2+} (catalytically active form) in order to understand the extensive conformational changes that occur upon Mg^{2+} binding [57].

Du *et al.* used ^1H–^{13}C RDCs to refine the structure of Stem-Loop D from the cloverleaf RNA which binds to viral proteins [41]. This RNA molecule contains a tandem pyrimidine mismatch that may play a role in protein recognition as shown in Figure 2. This example provides a dramatic illustration of the power of RDCs in nucleic acid structure determination. Without RDCs, overall convergence is quite poor and it is impossible to overlay both stems simultaneously. RDCs lead to a noticeable improvement in the overall structure and allow features which pertain to function, such as the helical propensity and deformations due to the pyrimidine mismatches to be observed.

Pseudocontact Shifts

Paramagnetic metals cause the molecule to become aligned in the magnetic field due to the large magnetic susceptibility anisotropy. The anisotropy of the molecule also allows RDCs to be measured. It also leads to Pseudocontact Shifts (PCS), another source of orientational data that is due to the dipolar interactions between the unpaired electron and the nuclear spin. The PCS effect can be observed over large distances, as far as 40Å from the metal site [58]. The form of the PCS equation is similar to the equation for RDCs.

$$\delta_i^{pc} = \frac{1}{12\pi r_i^3}\left[\Delta\chi_{\mathrm{ax}}(3\cos^2\theta - 1) + \frac{3}{2}\Delta\chi_{\mathrm{rh}} \times (\sin^2\theta\cos 2\phi)\right] \tag{2}$$

where $\Delta\chi_{\mathrm{ax}}$ is the axial component and $\Delta\chi_{\mathrm{rh}}$ is the rhombic component of the magnetic susceptibility tensor, respectively. The program FANTASIAN can be used to calculate the magnetic susceptibility tensor [59].

The PCS can be obtained by taking a diamagnetic metal-binding protein and titrating it with a paramagnetic metal [60]. Lanthanides (Ln^{3+}) are preferred for this purpose due to their high magnetic susceptibility tensor. Each Ln^{3+} has a different magnetic susceptibility tensor. Therefore, by using several different lanthanides it is possible to obtain numerous, non-redundant PCS and RDC data sets, which increases the number of input restraints in structure calculation.

Calmodulin (CaM) has been used in many examples of PCS/RDC structural analysis and ligand-induced conformational changes. CaM consists of an N and C-terminal domains, each of which binds Ca^{2+}, that are connected by a linker. Metal binding leads to a change in conformation that allows binding to the target molecule to occur. The dynamic properties are such that the 2 domains can behave independently (apo form) or as a single entity (protein-bound form). Ln^{3+} ions titrate preferentially into the N-terminal and in the case of Tb^{3+}, but the magnetic susceptibility is strong enough that the PCS effect is detected in residues located in the C-terminus [61]. For each residue, several peaks are observed in the NMR spectrum corresponding to the different Ca^{2+}/Ln^{3+} combinations. Disappearance of these signals can be used to monitor the extent of the titration. However, the presence of peaks corresponding to the diamagnetic and paramagnetic species in a single spectrum can cut down on experiment time. Line broadening is an inherent property of paramagnetic metals that can be problematic if too many individual resonances become obscured. Therefore, when choosing which Ln^{3+} to use one must weigh the strength of the magnetic susceptibility tensor against the line broadening effects.

Just as RDC data can be used to determine the relative orientation of separate protein domains, so too can PCS data. Studies of apo-CaM with Tb^{3+} and Tm^{3+} were performed and used to establish that the protein samples a range of conformations in a non-uniform manner. The C-terminal domain moves with respect to the N-terminal domain in an elliptical region with a cone angle of 30° [62]. A PCS study of meltonin-bound CaM with Tb^{3+} substituted for Ca^{2+} showed that motion in the N and C domains occurs independently from one another, similar to previously characterized apo-form of CaM [63].

Analogous to RDCs, PCS data can be used in structure refinement. Protocols for using PCS data within Xplor-NIH (PARArestraints) [64] and PARAMAGNETIC DYANA [65] have been developed which are similar to those used for RDC data. PARArestraints also allows implementation of other types of paramagnetic data such as paramagnetic relaxation enhancements, and Curie-dipolar cross correlated relaxation. Structures which have been refined with PCS data include cyctochrome *c* [66], a DNA octamer bound to chromomycin-A_3 [67] α-parvalbumin [68].

It is possible to obtain PCS data from non-metal binding diamagnetic proteins. Several laboratories have devised ways to attach paramagnetic metals by using paramagnetic 'tags' [69–72]. Two cysteine residues are engineered onto the protein surface to allow site-specific binding to a derivative of DTPA, a bidentate lanthanide-containing molecule. Modified EDTA molecules can be used in a similar manner. Incorporation of these small ligands ensures that there is no dynamic behavior relative to the protein, i.e. both the tag and the protein have the same magnetic susceptibility tensor. Other techniques include engineering short paramagnetic-binding peptides to the protein termini [73,74].

Unfolded Denatured Proteins

As alluded to previously, the nature of the information derived from RDCs makes them ideal for examining almost any type of structural perturbation including changes in proteins as they undergo unfolding. Intuitively, one would expect that unfolding leads to averaging of any preferred orientation resulting from alignment which would reduce the magnitude of RDCs close to zero. However, theoretical studies by Annila and co-workers have shown that short polypeptide chains have a bell-shaped non-zero RDC distribution [75]. This finding has been born out in experimental studies as well, as first demonstrated for staphylococcal nuclease [76]. Other proteins too have shown to have what is referred to as persistent helical structure or native-like topology. Ohnishi *et al.* found in the case of unfolded eglin C, that the correlation between measured and calculated RDCs was inversely proportional to chain segment length and that denatured eglin C analyzed with RDCs showed native-like topology [77]. Eglin C shows a range of RDC values and not "monotonic" values as would be expected for a random chain. A study of equilibrium intermediates of apomyoglobin supports the argument that unfolded proteins contains conformational segments of 5–7 amino acids in length which take on extended conformations and behave in an anisotropic manner which explains the observation of non-zero RDCs [78].

Looking at the N-terminal domain of the stem-loop binding protein, Thapar *et al.* used RDCs based on the concept that in a helical region the ^1H–^{15}N amide RDCs should correlate with the angular periodicity within the helix with respect to the long axis of the helix, also known as "dipolar waves" [79] to ascertain that the protein contains very little persistent tertiary structure [80]. However, denatured acyl coenzyme A binding protein (ACBP) was shown to have residual secondary structure in 4 distinct regions. Subsequent RDC analysis on an unfolded mutant of ABCP demonstrates that one of these regions is stabilized by hydrophobic interactions [81]. Unfortunately it is not possible to use these data to determine the structure of unfolded proteins because there is no unique alignment tensor for the molecule as a whole. RDCs have been used to monitor the unfolding process such as in the case of GB1 where RDC values as a function of temperature were monitored in order to locate 2 specific thermal unfolding hot spots [82].

Oligosaccharides and Small Organic Molecules

The application of RDCs to carbohydrates suffers from some of the same drawbacks as with nucleic acids: relatively few ^1H–^{13}C bonds (most of which have a similar i.e. parallel, orientation), low proton density, etc. In addition, flexibility around the glycosidic torsion angle means that at the outset it must be assumed that each monosaccharide has a distinct alignment tensor which makes it difficult to measure enough RDCs for each ring to determine the alignment tensor. Differences in alignment tensor values for monosaccharides within a given oligosaccharide can be attributed to motion around the glycosidic torsion angles [83]. Several groups have described how to circumvent these problems and have introduced strategies for determining oligosaccharide structures. Griesinger and co-workers included measurement of ^1H–^1H RDCs to supplement the ^1H–^{13}C RDCs in the structure determination of raffinose and saccharose so that the alignment tensor can be determined with greater accuracy [84]. Inclusion of ^1H–^1H RDCs radically improves the precision of structures as the RMSD is decreased by a factor of 3. Cross-validation was used to determine how closely the NMR structure matched the corresponding crystal structure. For raffinose, significant differences were found in the Glc-Fru torsion angles compared to both crystal structures and previous NMR structures.

The three-ring Lewis blood group motifs are ideal systems for study because it has been established that they exist in single, rigid conformations. Therefore the five required RDCs needed for determination of the alignment tensor do not have to be extracted from a single pyranose ring. Martin-Pastor and Bush have demonstrated approaches using ^{1}H–^{13}C RDCs to determine structures of oligosaccharides containing various Lewis motifs. They were able to determine the structure of a pentasaccharide by first solving the structure of the Lewis A motif within the pentasaccharide and then determined the orientation of the two remaining sugars with respect to the Lewis A motif [85]. In a continuation of these studies, RDCs were used to determine the structures of 5 different Lewis blood group-containing oligosaccharides and as an aid in sorting out ambiguities in the NOE and molecular mechanics data. The conformations of these oligosaccharides were determined using a grid-search protocol which was feasible because of the relatively low number of degrees of freedom [86]. Similar studies using Monte Carlo methods to determine the structures of Lewis motifs indicated variations in dihedral angles between different low-energy conformations of 10° for the ϕ dihedral angle for the Fucα (1-3) GlcNAc [87]. Berthault *et al.* have used carbohydrates containing Lewis motifs to investigate whether or not oligosaccharides interact with the alignment media and found that larger more flexible oligosaccharides do interact with the media [88].

RDC studies on oligosaccharides have been used to understand some of their dynamic properties and how that may affect molecular recognition. In oligosaccharides, the relative amplitude of motion of each saccharide around the glycosidic bond can be determined by differences in the alignment tensor parameters in the form of the general degree of order (GDO) [89]. Yi *et al.* have demonstrated a novel technique for investigating conformations and motion in a disaccharide [90]. By attaching an alkyl chain to one end of the disaccharide which protrudes into the bicelle and immobilizes that end of the disaccharide, the overall alignment tensor becomes equivalent to that of the bicelle and the degrees of freedom in the number of parameters describing the glycosidic motion decreases.

In structural studies of small organic molecules, stereochemical assignments are very difficult and NOEs and scalar J couplings are not always adequate for distinguishing different types of protons. These assignments can be quite useful for understanding interactions between small organic compounds and proteins or DNA. A general strategy is to compare measured and calculated RDCs in order to identify which resonance corresponds to a particular proton. Thiele and Berger were able to unambiguously distinguish between two methylene protons in strychnine simply by comparing the measured and calculated RDCs for the two protons in question and then subsequently, assigned all pairs of diastereotopic protons in strychnine [91,92]. A similar methodology was used by Verdier *et al.* to determine the relative stereochemistry in menthol [93]. Yan *et al.* demonstrated that the relative stereochemistry of 6-membered rigid rings could be determined without any order-matrix calculations [94]. In this strategy, if one knows that a specific C–H bond vector is in an axial or equatorial configuration, that the configuration of other C–H bonds can be determined based on whether the RDC value is similar to that of the RDCs for the known configuration. Aroulanda *et al.* showed how to determine the cis or trans conformation of dihydropyridones based on the idea that two particular C–H bonds in the molecule should parallel and therefore similar orientations and similar RDC values in the *trans* conformation but would have non-parallel, dissimilar orientations, and dissimilar RDCs in the cis conformation [95]. Some of the commonly used alignment media for small organic molecules include poly-γ-benzyl-L/D-glutamate (PBLG and PBDG) in chloroform [96] and poly-γ-ethyl-L-glutamate (PELG) [92]. Mangoni *et al.* have demonstrated how to determine the relative configuration of stereocenters in sodium cholate to determine the relative stereochemistry of two stereocenters [97].

Conclusions

In this short review we have provided an overview of the most recent RDC applications. The breadth of topics that RDCs are being used to address is impressive, particularly because many of these applications are directed at understanding the dynamic nature of biomolecules which is the essential bridge linking static structure and physiological function. Undoubtedly, this field will continue to expand and new methods will be introduced to use RDCs to solve some of the most challenging structural biology questions, particular with respect to molecular recognition and conformational dynamics.

Refinement of Nucleic Acid Structures with Residual Dipolar Coupling Restraints in Cartesian Coordinate Space

Nikolai B. Ulyanov, Zhihua Du, and Thomas L. James
Department of Pharmaceutical Chemistry, University of California at San Francisco, San Francisco, CA 94143-2280, USA

Introduction

During the past decade, measurement of residual dipolar constants (RDC) in weakly oriented molecules has been established as an invaluable source of structural information, and RDC data are now often used in structure determination of biological macromolecules via NMR [1–4]. Indeed, incorporation of RDC data in nucleic acid structure refinement apparently improves the accuracy and precision of global conformations and possibly local conformations as well [5–7].

Traditional (without RDC) refinement of solution NMR structures involved short-range structural restraints derived from the nuclear Overhauser effect (NOE) and from scalar J-coupling data: interproton distances and torsion angles, respectively. The degree of structure definition under such circumstances depended on the number of structural restraints and on their precision and accuracy. With proper care, local conformations could be accurately refined to a high degree of definition but, due to error propagation, the global structure was defined less precisely and perhaps less accurately. The situation is more severe for nucleic acids than for proteins, because errors propagate more efficiently in nucleic acids due to their typically elongated shape. Besides, nucleic acids have a smaller proton density and uneven spatial distribution of protons. In particular, phosphodiester groups do not have protons, and the only residues with nonexchangeable protons in the bottom of the minor groove are adenines (with H2 protons). Adenine H2 protons have NOE contacts across the minor groove with protons from the opposite strand [8,9], which help define better the local conformation. Sequences lacking or having only few adenines are therefore inherently worse defined by the NOE data.

In an effort to overcome these problems, several groups, mostly working in the field of DNA structure determination, have been developing methods to use NOE data quantitatively. Instead of deriving approximate interproton distances under the isolated spin pair approximation, these methods are based on calculation of the complete matrix of dipole–dipole relaxation rates, which are responsible for observed NOE intensities [10–12]. Practically, structures were determined either by incorporating NOE calculations into the refinement program [12–15] or with the help of an iterative procedure to determine the interproton distances [16–19]. An approach extensively used in our lab involved an iterative complete relaxation rate matrix-based procedure, MARDIGRAS, to calculate interproton distances from NOE intensities, which was subsequently extended to include a random error analysis [20,21] and to take into account partial relaxation [22]. This approach allowed determining accurate and well-defined solution structures of relatively short (1–1.5 helical turns) fragments of nucleic acids [23–27]. However, the degree of definition of the global conformation suffered considerably for larger multi-domain structures [28,29]. In fact, even the definition of the local conformations depended critically on the number and distribution of experimental restraints, although complete relaxation matrix-based methods were used [24,30,31].

The situation has improved dramatically with the incorporation of RDC data into refinement protocols [4,32]. The contribution of the through-space dipole–dipole interactions to spin–spin splitting of resonances is normally averaged to zero in isotropic solutions. However, if a macromolecule is weakly oriented relative to the magnetic field, such as in a dilute liquid crystalline solution, the average RDC is nonzero and depends on the molecular alignment tensor, the orientation of the dipole–dipole vector relative to the alignment tensor, and the internuclear distance. RDC data can be readily incorporated into refinement algorithms, especially for nuclei connected with a single bond, when the internuclear distance r is fixed. RDC data depend on r^{-3} rather than r^{-6}, as with NOE data, so they are more sensitive to longer range dipole–dipole interactions: this, together with the dependence of RDC values on orientation, should improve dramatically the degree of definition of the global conformation, even for multi-domain structures. Indeed, refinements using simulated data have shown that addition of RDC restraints improved greatly the accuracy and precision of both local and global conformations of DNA duplexes containing A-tracts [5,6]. Using RDC data quickly became the method of choice for determining NMR solution structures of nucleic acids: DNA [33–40] and especially RNA [7,41–48].

RDC restraints have been implemented in several refinement packages, including the NIH version of XPLOR [49,50], DYANA [51], AMBER [52], and SCULPTOR (a modified version of the DISCOVER package, MSI) [53]. AMBER and SCULPTOR perform structure refinements in the Cartesian coordinate space, while DYANA performs refinements in the space of internal coordinates, specifically, torsion angles. XPLOR is capable of structure calculations in both Cartesian and torsion angle space. The NIH version of XPLOR is the most widely used package for RDC refinements, which includes many new NMR-oriented options, in particular a new code for refinement in torsion angle space [54]. Torsion angle dynamics is indeed a recommended option for NMR refinements [49], because of its efficiency. Unfortunately, in many published applications, authors do not state explicitly if the refinement was carried out in torsion angle or Cartesian coordinate space. Our recent experience with refinement of RNA structures in Cartesian coordinate space using AMBER 7 showed that RDC restraints require special treatment [47], which we discuss below. We will describe structural refinement protocols in the context of functionally significant RNA fragments from enteroviruses.

Loop B RNA from Domain IV of the Enterovirus Internal Ribosome Entry Site

Enteroviruses, members of the Picornaviridae family, are positive single-stranded RNA viruses; Poliovirus is a typical example of an enterovirus. The genomic RNA of enteroviruses is uncapped; the internal ribosome entry site (IRES) sequence, a part of the 5′-untranslated region (5′-UTR), mediates a cap-independent translation by allowing ribosomes to enter mRNA internally. In addition, with help from viral and host protein factors, IRES controls a switch from protein synthesis to negative-strand RNA replication [55]. The secondary structure of 5′-UTR is predicted to have six distinct domains, with domains II–VI forming the IRES [56]. In the absence of the viral protein 3CD, loop B of domain IV is bound by a host protein, polyC-binding protein 2 (PCBP-2) with a dissociation constant of 15 nM [57]; this complex promotes viral translation. When levels of the 3CD protein are sufficiently high, 3CD forms a ternary complex with PCBP-2 and domain I of the 5′-UTR, the cloverleaf structure, with the dissociation constant of 1 nM. As a result, PCBP-2 dissociates from the lower-affinity site on loop B of domain IV. These events inhibit the viral translation and trigger the start of viral RNA replication.

The secondary structure of loop B of domain IV is strongly conserved, with a GNRA apical tetraloop and a cytosine-rich six-nucleotide asymmetric internal loop (bulge) in the middle of the stem. Although not absolutely conserved in sequence, the six-nucleotide bulge is cytosine-rich in all enteroviruses [47], and the cytosine residues are required for both virus translation and PCBP-2 recognition [57]. We have solved NMR structures of two natural sequence variants of the loop B RNA from enteroviral domain IV using quantitative interproton distance restraints, torsion angle restraints and ^{13}C–H RDC restraints. Details of the refinements are published elsewhere [47]; here, we will briefly summarize them and focus on some aspects of using RDC restraints with the AMBER package. Sequences of the two sequence variants, 10C and 10U, are shown below.

```

For simplicity, only the 10C sequence variant will be discussed here.

Structural Restraints

The structural restraints for the 10C RNA included 575 distance restraints and 86 ^{13}C–H RDC restraints. Distance restraints included 281 quantitative restraints calculated with MARDIGRAS from the accurately integrated NOE intensities in homonuclear 2D NOESY data set acquired in D_2O, 97 qualitatively categorized distance restraints involving exchangeable protons from the 2D water NOESY, 72 6.0-Å upper bounds for peaks observed only in the 3D ^{13}C-edited NOESY spectrum, 88 non-NOE restraints (lower bounds of 5 Å) for proton pairs that did not have any intensity in any of the NOESY spectra, but tended to have a short distance in preliminary calculations, and 37 hydrogen bond restraints. In addition, torsion angle restraints were used for sugars consistent with C2′-*endo* conformation (residues 9–13 and 27 that showed a strong H1′–H2′ cross-peak in DQF-COSY spectrum) or C3′-*endo* conformation (the rest of the residues). Backbone torsion angle restraints consistent with a generic A-form were used for the stem residues.

Structure Refinement

Structures were calculated in three stages. At first, the DYANA 1.5 program [51] was used to carry out simulated annealing with 10,000 steps of torsion angle dynamics starting with 100 randomized initial structures; only distance and torsion angle restraints but no RDC restraints were used at this stage. The 50 best DYANA structures were passed to the SANDER module of AMBER 7 suite of programs [52] and refined with the same type of structural restraints (no RDC restraints). At the last stage, structures were refined further with SANDER using both distance restraints and RDC restraints.

Before the last stage, the structures had low residual distance and torsion angle restraint deviations but, as expected, high-residual RDC deviations. The root mean square (RMS) deviation between measured and predicted RDC values was 26.5 Hz on average for the 10 best structures. To calibrate the force constant for the RDC restraints, we carried out three series of test calculations, performing short restrained minimizations with distance, torsion angle, and RDC restraints. The RDC force constant was kept at 0.001, 0.01, or 0.1·kcal/mol/Hz^2; these values are below of those typically used for the RDC refinements, e.g. [44]. While the lowest force constant had little impact on the structures and calculated RDC (average RMS of 25.4 Hz), the response was very strong for higher force constants: average RMS between observed and calculated RDC values decreased to 12.9 and 5.9 Hz for force constants of 0.01 and 0.1 kcal/mol/Hz^2, respectively. Individual structures had RMS deviations as low as 2.4 Hz. This was an unexpected result, because minimization in the Cartesian coordinate space, either restrained or free, usually has very little effect on global conformations. Indeed, the global structures changed little after the minimization with RDC restraints, with an average atomic RMSD of 0.13 Å (Figure 1A). Close inspection of the structures showed, however, that the improvement of the RDC restraints came at the expense of the local valence geometries (Figure 1B). In the Cartesian coordinate-based methods, the positions of individual atoms are free to change, and the resulting bond angles are determined by a number of energy terms in the force field [58]. Introduction of foreign terms into the force field, such as experimental restraint energy, has the potential to distort the idealized local conformations. We have noticed in the past a similar problem when using distance restraints with AMBER refinement [59], but the distortions were not as severe in that case.

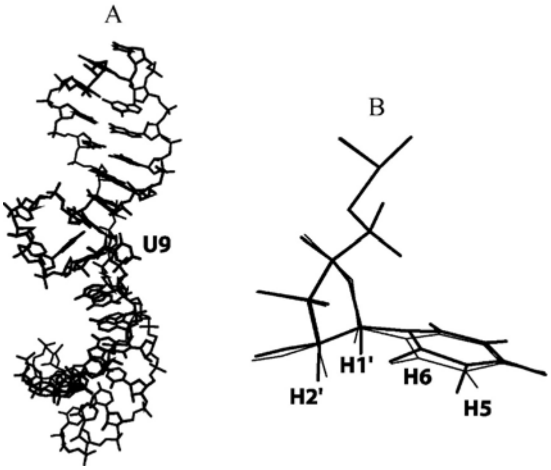

Fig. 1. Superposition of the 10C RNA structure refined with the distance and torsion angle restraints with the structure, which had been further restrained–minimized with the RDC restraints. (A) Global conformations are essentially identical, with the atomic RMSD 0.1 Å. (B) Residue U9 of the same superposition. The structure minimized with the RDC restraints is shown with thin lines. A distorted local conformation is apparent for this structure. This picture was generated with the graphics program MidasPlus [64].

A similar problem has been encountered by others [41,60]. To reduce distortions of local geometries caused by orientational RDC restraints, force constants responsible for the planarity of bases were increased during the refinement of a theophylline-binding RNA aptamer [41], and additional bond angle restraints were introduced reinforcing the ideal protein backbone geometry during the refinement of a protein–DNA complex [60]. When we attempted a similar approach for refining the 10C RNA structure, it indeed improved the geometries of the nitrogenous bases; however, the local geometries of sugar rings became even more distorted (not shown). Specifically, ribose rings became “average” and flatter: typically, the pseudorotation phase angle became 80°–90° (average between C2′-*endo* and C3′-*endo*), and the amplitude of pseudorotation ca. 10° (typical values of the amplitude must be in the range of 35°–40°). The reason for this is clear. All endocyclic bond angles in a ribose have an equilibrium value of 109.5° in the AMBER parm94 force field. This corresponds to an almost flat geometry of sugar rings (equilibrium values of 108° would correspond to perfectly planar geometry). It is a balance of the bond angles potential and torsion angles potential that keeps the sugar geometry reasonable; by increasing the weight of the bond angles term, we distorted the equilibrium local geometries.

Table 1: Bond angles (degrees) involving hydrogen atoms in sugar–phosphate moieties

Atoms	C2′-*endo*	C3′-*endo*
N1/N9–C1′–H1′	109.6	109.5
C2′–C1′–H1′	109.6	109.5
O4′–C1′–H1′	109.6	109.5
C1′–C2′–H2′	109.7	111.8
C3′–C2′–H2′	109.7	111.8
O2′–C2′–H2′	109.7	111.8
C2′–C3′–H3′	111.5	109.4
C4′–C3′–H3′	111.5	109.4
O3′–C3′–H3′	111.5	109.4
C3′–C4′–H4′	108.6	108.8
C5′–C4′–H4′	108.6	108.8
O4′–C4′–H4′	108.6	108.8
C4′–C5′–H5′/H5″	108.9	108.9
O5′–C5′–H5′/H5″	108.9	108.9
H5′–C5′–H5″	109.5	109.5

The endocyclic bond angles in the sugar ring depend on a particular sugar pucker. A survey of geometric parameters observed in high-resolution crystal structures of nucleosides and nucleotides has been published, separately for C2′-*endo* and C3′-*endo* sugar puckers [61,62], and the data for the heavy atoms are available in a computer-readable form from the NDB Nucleic Acid Database [63]. To generate similar parameters involving protons on riboses, we carried out the following procedure. At first, separately for C2′-*endo* and C3′-*endo* conformations, we generated bond length and bond angle restraints using the data for the heavy atoms from the published survey [62]. Using these restraints, we carried out restrained AMBER minimization on a nucleotide unit, with force constants of 1000 kcal/mol/Å^2 and 1000 kcal/mol/rad^2 for distances and angles, respectively; protons were left unrestrained. Then, using heavy atoms of the calculated structures, we calculated new proton positions using geometric considerations. Specifically, the CH bond length was assumed to be 1.09 Å. A proton in the CH group was placed on a line forming equal angles with all proximal CX bonds. For example, for the H1′ proton, angles H1′–C1′–N9, H1′–C1′–C2′, and H1′–C1′–O4′ are equal. Protons H5′ and H5″ are placed on the bisector plane to O5′–C5′–C4′ such that the H5′–C5′–H5″ angle adopts a tetrahedral value. The resulting bond angles involving protons are summarized in Table 1.

Published data for the heavy atoms [62] and data of Table 1 for protons were used to prepare bond length and bond angle restraints reinforcing the local geometries of sugar–phosphate moieties for the 10C RNA. These restraints depend on sugar pucker: C2′-*endo* for residues 9–13 and 27, and C3′-*endo* for the rest of the residues. Similar restraints and improper torsion angle restraints were generated for nitrogenous bases using the parm94 parameters. Altogether, several thousand such local geometry restraints were generated, with force constants of 1000 kcal/mol/Å^2 and 1000 kcal/mol/rad^2 for distances and angles, respectively. For the experimental NOE distances, non-NOE restraints, and hydrogen bond restraints, a force constant of 10 kcal/mol/Å^2 was used. For sugar pucker restraints and backbone torsion restraints, a force constant of 100 kcal/mol/rad^2 was used. The force constant for the RDC restraints was 0.2 kcal/mol/Hz^2. These restraints were used with the simulated annealing protocol as described [47] to calculate the RNA structures; the global conformations were adjusted according to the RDC restraints, but the local conformations remained undistorted. The only unusual feature of this protocol was the requirement of tighter-than-usual coupling to a thermal bath. Because the large number of local geometry restraints work against the force field for the sugar rings, it may create large local forces. The integration step for MD simulations was decreased to 0.5 fs (integration step as low as 0.2 fs has been reported for MD refinements with RDC restraints) [35]. In addition, the parameter TAUTP, which defines in AMBER the coupling to the thermal bath, was varied during the trajectory as shown in Figure 2A.

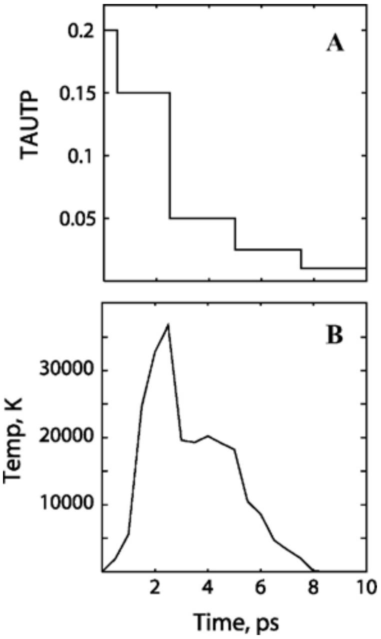

Fig. 2. Refinement protocol with RDC restraints. (A) Parameter TAUTP defining the coupling to the thermal bath. (B) Temperature recorded in a typical trajectory.

The actual temperature reading during a typical trajectory is shown in Figure 2B.

In conclusion, special care must be given to RDC restraints when used in refinement protocols in the Cartesian coordinate space. Using a large number of sugar pucker-dependent restraints, reinforcing the local geometry allows refinement of global structures without distorting local conformations. Incidentally, the same approach prevents distortions of local conformations due to NOE-derived distance restraints. Such a problem does not exist for refinement protocols in internal coordinate space, such as implemented in XPLOR; therefore the refinement protocols are simpler, see, e.g. [7]. However, flexibility in choosing the refinement method is useful. In particular, AMBER refinements with RDC restraints have a very helpful option of adjusting the alignment tensor in the course of the refinement.

Conformational Analysis of DNA and RNA

Gota Kawai
Faculty of Engineering, Chiba Institute of Technology, Chiba 275-0016, Japan

Introduction

As is the case for proteins, NMR methods have been applied to DNA and RNA extensively and methods for the structure determination by NMR are recently almost established [1–6]. In this section, a general view of the NMR application for DNA and RNA is shown.

DNA or RNA consists of four kinds of nucleotides (Figure 1). Nomenclature for DNA and RNA in NMR can be found in Ref. [7]. The bases form the Watson–Crick type base pairs, A-T (A-U in RNA) and G-C, and stack to each other to form the double helix structure, or a stem. Due to the conformational flexibility of the nucleotide residues, DNA can form three types of stems, A, B, and Z forms. On the other hand RNA forms the A-type stem dominantly [8]. However, this does not mean that RNA structure is simple. RNA forms tertiary structures including loop, bulge, or internal loop as well as long-range interactions to express their biological functions.

Conformation of Nucleotides

As shown in Figure 1, each nucleoside consists of at least two rings, base and ribose, and this restrict the conformation of nucleosides, leading that relatively small number of information can work for determination of conformational characteristics. Figure 2 shows the torsion angles in nucleic acids and Figure 3 shows the possible conformations of nucleosides. The puckering of ribose or deoxyribose plays most important role for the conformation of nucleic acids. The puckering mainly in the C2′-*endo* or the C3′-*endo* forms (Figure 3a). The conformation of ribose or deoxyribose ring is generally described by the pseudorotation (P) angle [7,9] and the C2′-*endo* and C3′-*endo* forms are also donated as the S and N form, respectively. The rotation around the glycosidic bond (x angle, Figure 3b) depends on the puckering. The rotation around the C4′–C5′ (the y angle, Figure 3c) is dominantly in the gg form and also depends on the puckering. For review of the nucleotide conformation, see Ref. [8].

NMR Signal for DNA and RNA and Their Assignment

Figure 4 shows the typical ^{1}H chemical shift range for nucleic acids. Imino protons in base pairs resonate in lower field and give better separations compare to other resonances in nucleic acids although the line width is larger due to the dynamic process. The immobile protons for RNA, especially H2′–H5″, resonate in narrow regions to make the signal assignment rather difficult.

Imino Proton Signals

Imino proton resonances give quite useful information for the secondary structure and tertiary interaction as well as the structural change. Each Watson–Crick base pair gives an imino proton resonance. The imino protons easily exchange with the proton of solvent and measurements are performed for RNA samples in typically 95% H_2O/5% D_2O solution with solvent signal suppression. In RNA, G-U and G-A base pairs are frequently found. The first step of the signal assignment is the discrimination of the kind of bases for each imino proton signals. As shown in Figure 4, chemical shift regions for each imino proton signal are somehow overlapped to each other. NOESY spectra give information for the difference between imino proton signals due to the A-U and G-U pairs. G-U pairs give two imino proton signals and strong NOEs between the two imino protons. The ^{15}N chemical shifts give clear indication for base type information [10]. Assignment of the imino proton resonances is mainly based on the sequential connectivity through NOE between imino protons of adjacent base pairs. This is similar to the case of main chain assignment for proteins. However, it should be in mind that, in the case of imino proton of DNA/RNA, assignments are based on the assumption of the formation of the secondary structure.

Immobile Proton Signals

The strategy for signal assignment for immobile protons is based on the well-known sequential assignment [1]. Although stable isotopic (SI) labeling has been introduced

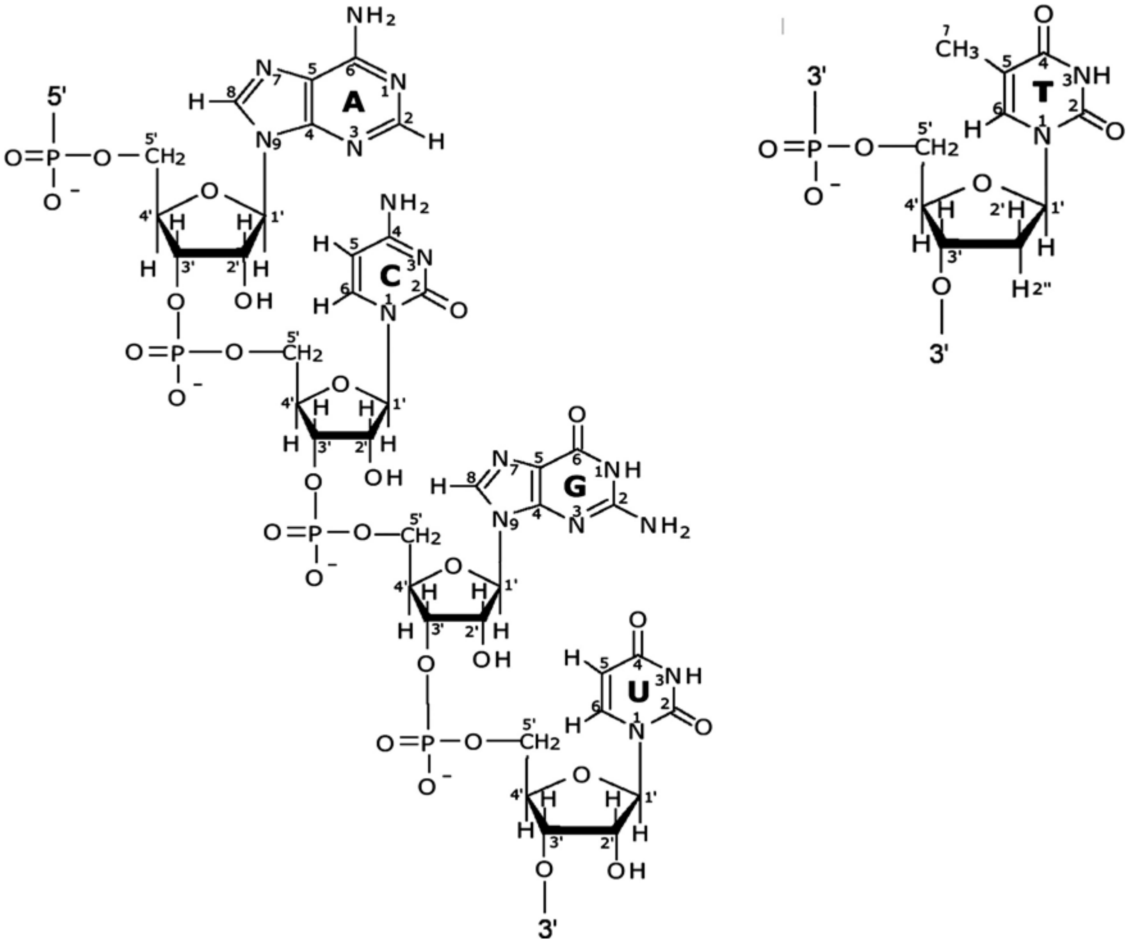

Fig. 1. Chemical structure of RNA and DNA. In DNA, 2′-OH of ribose and H5 of uracil base are replaced to H2″ and 7-CH_3 to form deoxyribose and thymine base, respectively.

to the analysis of RNA, the assignment is in many cases depends on inter-residue NOEs between base–ribose and base–base protons. This is because of the poor dispersion of chemical shift for ^{1}H as well as ^{13}C nuclei of RNA main chain, P–O5′–C5′–C4′–C3′–O3′. TOCSY or HOHAHA experiment is effective to analyze the ribose spin system as is the case for oligosaccharide. In the case of DNA, the presence of two protons, H2′ and H2″, at the second position of the ribose ring makes the coherence flow effective. With the appearance of H2′/H2″ in the deference chemical shift region with other protons, the TOCSY experiment is successive. In the case of RNA, the small value of J(H1′–H2′) for stem region in which the ribose takes the C3′-*endo* form makes the TOCSY spectrum poor. Thus, HCCH type experiments [11,12] with ^{13}C-labeled RNA sample must be required to obtain the information for the intra-residual correlation between H1′ and H2′. The relayed HOHAHA type experiment, which originally applied for the oligosaccharide in which the coupling between H4 and H5 is generally small, may overcame the small coupling problem in ribose moiety [13].

Phosphorus Signals

Although ^{1}H–^{31}P correlations are important information for the sequential assignment through main chain of nucleic acids [5], use of them is sometimes difficult due to the severe overlap of ^{31}P signals and ^{31}P chemical shift anisotropy. Because the energy of transition as well as natural abundance of ^{31}P is high enough, ^{1}H–^{31}P correlation

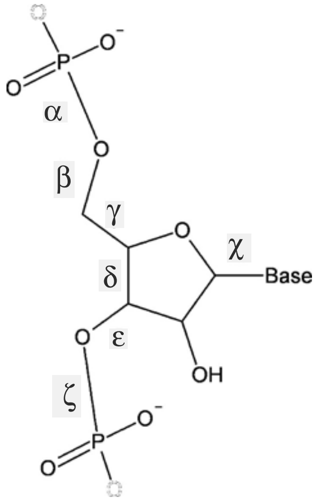

Fig. 2. Torsion angles in nucleic acids.

experiment can be started from the ^{31}P magnetization [14–16]. ^{17}O-labeling is a possibility to make unambiguous assignment of ^{31}P signals for nucleic acids [17].

Stable Isotopic Labeling

The SI labeling is powerful tool for the NMR analysis of biomacromolecules and SI labeling, ^{13}C and ^{15}N, for RNA is also being the standard techniques [4,5,10] as shown above. SI-labeled DNA and RNA can be prepared either by chemical synthesis or by enzymatic synthesis. The SI-labeled phosphoroamidite units and nucleotides triphosphates (NTPs) can be obtained commercially. Furthermore, custom synthesis of SI-labeled oligonucleotides, DNA as well as RNA, is also available. Residue-specific labeling or segment-specific labeling is quite useful to make unambiguous assignment. Chemical synthesis as well as enzymatic synthesis can be used for such kind of labeling [18–21]. Fractional ^{2}H labeling might be important to reduce the proton density and increase the sensitivity for larger RNAs as applied for larger proteins.

Structural Analysis

Conformation of Nucleosides

The conformation of nucleotides can be analyzed in detail by NMR, the spin–spin coupling constants (J) and NOEs. In the case of nucleosides and nucleotides, the conformation is not fixed but in the conformational equilibrium. Thus, fractional population of each conformer must be obtained. The puckering can be analyzed by the J(H1′–H2′) and J(H3′–H4′) values with the well known

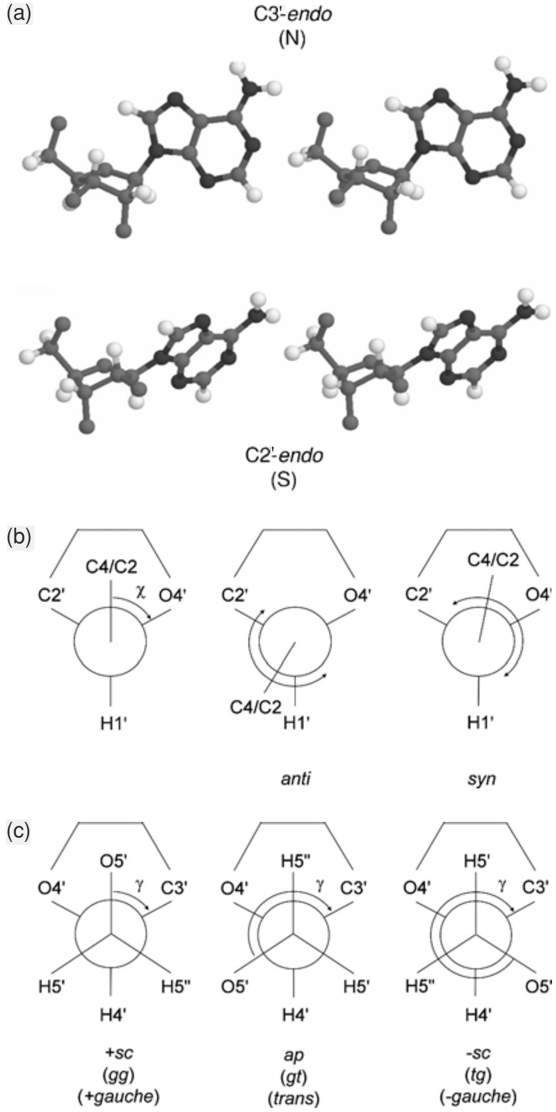

Fig. 3. Conformations of nucleotides. (a) Sugar puckering. The C2′-*endo* form is corresponding to the range of $P = 0^\circ$–18° and the C3′-*endo* form is to the range of $P = 144^\circ$–162°. (b) Rotation around the glycosidic bond (χ). In the case of the C2′-*endo* form, the χ angle is dominantly in between 180° and 216° which is in the range of the *anti* conformation. In the case of the C3′-*endo* form, the χ angle can be in the ranges of the *anti* form (216°–252°) or the *syn* form (36°–72°). (c) Rotation around the C4′–C5′ bond (γ).

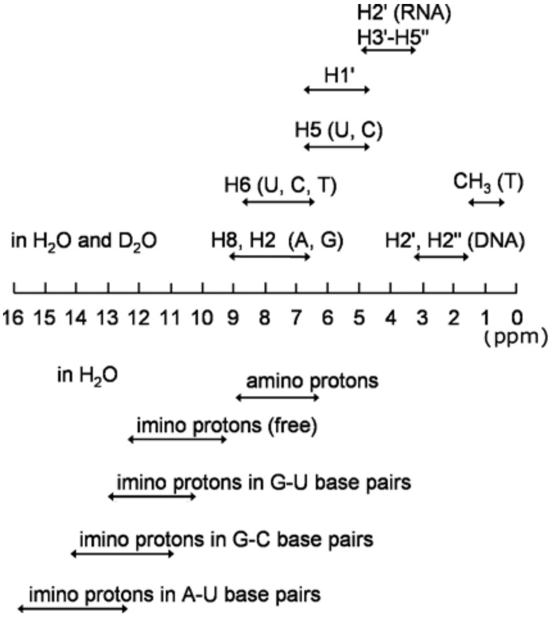

Fig. 4. ^{1}H chemical shift ranges for DNA and RNA.

equations,

$$X(\mathrm{C2'}-endo) = J(\mathrm{H1'}-\mathrm{H2'})/[J(\mathrm{H1'}-\mathrm{H2'}) + J(\mathrm{H3'}-\mathrm{H4'})] \quad (1a)$$

$$X(\mathrm{C3'}-endo) = J(\mathrm{H3'}-\mathrm{H4'})/[J(\mathrm{H1'}-\mathrm{H2'}) + J(\mathrm{H3'}-\mathrm{H4'})] \quad (1b)$$

where X(C2′-*endo*) and X(C3′-*endo*) are the fractional populations for the C2′-*endo* and C3′-*endo* forms, respectively [22]. For standard nucleosides and nucleotides, the value of J(H1′–H2′) + J(H3′–H4′) is always close to 10 Hz and, thus, the X(C2′-*endo*) and X(C3′-*endo*) can be estimated only with the J(H1′–H2′) values. The puckering of nucleosides and modified nucleosides are extensively analyzed by NMR in relation to the translation of genetic code and stabilization of tRNA structure [23–26]. Relationship between the ribose conformation and chemical shift of base protons was found for 5-substituted uridine and cytidine [27,28].

The γ angle can be analyzed by the J(H4′–H5′) and J(H4′–H5″) values as follows [29].

$$X(\mathrm{gg}) = \{13.7 - [J(\mathrm{H4'}-\mathrm{H5'}) + J(\mathrm{H4'}-\mathrm{H5''})]\}/9.7 \quad (2a)$$

$$X(\mathrm{gt}) = [J(\mathrm{H4'}-\mathrm{H5'}) - 2.0]/9.7 \quad (2b)$$

$$X(\mathrm{tg}) = [J(\mathrm{H4'}-\mathrm{H5''}) - 2.0]/9.7 \quad (2c)$$

The γ angle is affected by the sugar puckering, the +sc is favored for the C3′-*endo* form and less favored for the C2′-*endo* form [30]. The ^{1}H–^{1}H coupling constants for standard nucleotides have been determined precisely in combination with the computer simulation of spectra to obtain precise values for coupling constants [31–35].

For the χ angle, NOEs between the base H8/H6 protons and ribose protons should be used. The NOE between H8/H6 and H1′ can be used to discriminate the *anti* and *syn* conformation qualitatively [1,36]. The χ angle can also be analyzed by the vicinal coupling J(^{13}C2/4-^{1}H1′) and J(^{13}C6/8-^{1}H1′) [37]. Spin coupling between phosphorus and proton can also be used for structure elucidation [6]. Typical values for J(^{31}P–^{1}H) values of P–O–C–H are summarized in Ref. [7]. J(^{31}P–^{13}C2′) and J(^{31}P–^{13}C3′) can be used for determination of the conformation around the C3′–O3′ bond [38].

Conformation of Oligonucleotides

For structural determination, following information is required: (i) inter- and intra-residual distances derived from NOE intensity, (ii) dihedral angles derived from spin coupling constants, and (iii) hydrogen bonding information derived from the analysis of imino proton resonances. In the case of RNA, stem structure is limited to the A-type double helix. Thus, the dihedral constraints fixing to the A-type ribose conformation may be introduced for the region where formation of stem is confirmed experimentally, for example, by sequential assignment of imino proton resonances. As described above, the puckering of ribose ring can be analyzed by the spin couplings. For larger RNA, it is sometimes hard to read the correct value of coupling constant especially for J(H3′–H4′) and, for such cases, the signal intensity of the H1′–H2′ cross peak on the HOHAHA spectra can be used for estimation of the puckering.

Hydrogen bonding can be directly detected by observing the N–N coupling [39,40] and this gives definite evidence for formation of base pairs such as the shared G-A pair [41,42].

3D Structure Determination

With enough number of distance and torsion constraints, the tertiary structure of DNA or RNA can be determined by simulated annealing calculation [5,43]. However, overall structures are sometimes not well converged due to the lack of long-range information in the case of DNA and RNA. This can be improved by using the residual dipolar couplings (RDC) during the refinement calculation as described below. It is noted that the local convergence can be detected by using the structural classification systems, CSNA [44,45].

For structure calculation of DNA and RNA having non-natural residues, force field parameters, especially electrostatic charges, for the specific residue is required. Basically, these parameters can be obtained by the *ab initio* quantum mechanical calculation [46,47]. However, recent program packages used for structure determinations have functions to treat non-natural residues and such systems were applied, for example, for modified nucleotides in tRNA [48,49] and artificial residues in designed DNA [50].

Residual Dipolar Coupling

Global information obtained from the RDC is quite useful for refinement of overall structures [51]. In the case of DNA and RNA, the Pf1 phage system is generally used for align the molecule [52,53]. Structural determination with RDC information is now being a standard method especially for larger RNAs [54]. RDCs are quite important for refinement of nucleic acid–protein complex structure [55–57]. In the presence of proteins, a dilute liquid crystalline medium may be used instead of the phage [58]. Also, RDCs can be used to estimate the relative orientations of stems for large RNA [59].

Part I

Solid-State NMR Technique

Analytical and Numerical Tools for Experiment Design in Solid-State NMR Spectroscopy

Niels Chr. Nielsen, Thomas Vosegaard, and Anders Malmendal
Center for Insoluble Protein Structures (INSPIN), Interdisciplinary Nanoscience Center (iNANO) and Department of Chemistry, University of Aarhus, DK-8000 Aarhus C, Denmark

Introduction

The solid-state NMR spectroscopy research area has evolved tremendously during the past few decades [1–4]. Initially a method of primary interest for physicists, it has become an increasingly powerful and widely used tool in materials science, chemistry, nanotechnology, and molecular biology. This development has been supported by scientific breakthroughs on many levels. First, on a general level, high-resolution solid-state NMR has to a great extent been inspired by the earlier developments of liquid-state NMR [5–7] which, due to simpler and easier controllable nuclear spin Hamiltonians, in many respects have set landmarks for our expectations to the ability of solid-state NMR for non-liquid samples. This applies in particular to biological samples, where the need for high resolution and sensitivity to establish structural constraints has set measures on the size and labeling strategies of molecules amenable to structural analysis. The expectations have been high, implying an enormous—and very constructive—drive on the development of methods capable of solving the most fundamental problems. Second, on the hardware level, solid-state NMR has been boosted by the same technological developments as liquid-state NMR: stronger magnets with better field homogeneity, providing higher sensitivity and improved spectral resolution. In addition to this comes the very important development of multiple-channel solid-state NMR probes with high radio-frequency (rf) power and fast magic-angle spinning (MAS) capabilities. Third, on the theoretical level, the introduction of average Hamiltonian theory (AHT) to solid-state NMR in the late sixties [8], and refinements of this method [9–11] as well as other analytical tools [12,13] has had a fundamental impact on the understanding of advanced NMR experiments and an application-driven systematic improvement of the fundamental experiments [1–4]. Fourth, on the computational level, the development of advanced numerical tools [14–18] has proven very useful for development and interpretation of solid-state NMR experiments in many disciplines. The two last elements are the topics of this contribution.

Tools for Systematic Experiment Design

Depending on their complexity and area of application, solid-state NMR experiments have for the past two to three decades been developed using appropriate combinations of intuition, analytical evaluations, numerical simulations, and experimental tests. Very often the inspiration to the design of a new experiment comes from the wish to improve an already existing experiment to perform better under similar or radically changed conditions. In other cases, not least applying to the rapidly developing field of biological solid-state NMR, the inspiration comes from a need to perform a given coherence or polarization transfer to obtain specific assignments or measurement of particular distances or torsion angles in the molecule. In the latter case, part of the inspiration may come from similar experiments (however, often governed by different spin interactions) known from liquid-state NMR. Taking out these motivating parameters and the final experimental tests, the design of solid-state NMR experiments has to a large extent been carried out using two tools, (i) AHT and (ii) numerical simulations. These tools may be used as complementary entities for systematic experiment design as illustrated in Figure 1.

Analytical Tools

One the most powerful tools for systematic development and evaluation of solid-state NMR experiments has been coherent averaging theory, AHT, or effective Hamiltonian Theory (EHT) as introduced in the context of multiple-pulse solid-state NMR by Haeberlen and Waugh in the late sixties [8]. In combination with appropriate transformation of the Hamiltonian into interaction

Graham A. Webb (ed.), Modern Magnetic Resonance, 679–687.

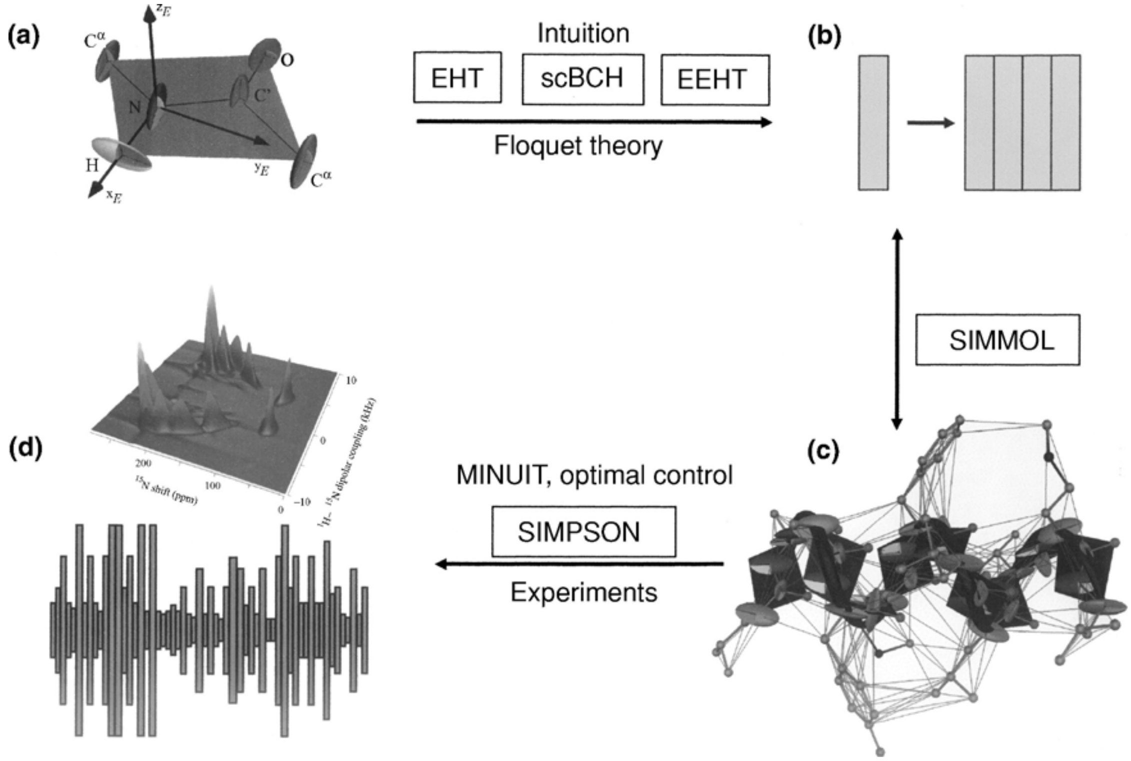

Fig. 1. Schematic illustration of tools used for systematic experiment design in solid-state NMR spectroscopy. Based on relatively small spin systems (often only one or two spins) (a) analytical tools, such as EHT, scBCH, and EEHT, may be used to refine crude "first-order" pulse sequences to more powerful "high-order" pulse sequence for tailoring the internal nuclear spin Hamiltonian, e.g. by re- or decoupling (b). By the use of general-purpose simulation programs such as SIMPSON along with programs for calculating typical tensorial interactions (SIMMOL) it is possible to extend the evaluation and design to realistic spin systems (c). Using these tools, along with non-linear optimization or optimal control, it is possible to systematically design pulse sequences with optimum performance for specific spin systems and calculate spectra to extract structural information (d). (See also Plate 62 on page XLIII in the Color Plate Section.)

frame(s) of the major external manipulations, EHT offers a relatively simple description of complex, time-modulated Hamiltonians in terms of an ordered series of effective-field Hamiltonians describing the overall effect of, e.g. multiple-pulse NMR experiments. The effective Hamiltonian may be written as

$$\bar{\tilde{H}}^{\mathrm{eff}} = \bar{\tilde{H}}^{(1)} + \bar{\tilde{H}}^{(2)} + \bar{\tilde{H}}^{(3)} + \cdots , \tag{1}$$

where the tilde indicates that the Hamiltonian is expressed in the interaction frame and the bar indicates "averaging" over a cycle period $\tau_c = t - t_0$. The ordered elements come from the so-called Magnus expansion and are defined as

$$\bar{\tilde{H}}^{(1)} = \frac{1}{\tau_c}\int_{t_0}^{t} \mathrm{d}t_1 \tilde{H}(t_1), \tag{2a}$$

$$\bar{\tilde{H}}^{(2)} = \frac{1}{2i\tau_c}\int_{t_0}^{t} \mathrm{d}t_1 \int_{t_0}^{t_1} \mathrm{d}t_2 \left[\tilde{H}(t_1), \tilde{H}(t_2)\right], \tag{2b}$$

$$\begin{aligned}\bar{\tilde{H}}^{(3)} = \frac{-1}{6\tau_c}\int_{t_0}^{t} \mathrm{d}t_1 \int_{t_0}^{t_1} \mathrm{d}t_2 \int_{t_0}^{t_2} \mathrm{d}t_3 \Big(\left[\tilde{H}(t_1), \left[\tilde{H}(t_2), \tilde{H}(t_3)\right]\right] \\ + \left[\tilde{H}(t_3), \left[\tilde{H}(t_2), \tilde{H}(t_1)\right]\right]\Big) ,\end{aligned} \tag{2c}$$

using the interaction frame Hamiltonian $\tilde{H}(t)$ and density operator $\tilde{\rho}(t)$ defined as

$$\tilde{H}(t) = U_{\text{int}}^{+}(t)H(t)U_{\text{int}}(t) - iU_{\text{int}}^{+}(t)\frac{\mathrm{d}}{\mathrm{d}t}U_{\text{int}}(t), \quad (3a)$$

$$\tilde{\rho}(t) = U_{\text{int}}^{+}(t)\rho(t)U_{\text{int}}(t), \quad (3b)$$

where $U_{\text{int}}(t) = T\exp\left(-i\int_{t_0}^{t}\mathrm{d}t_1\,H_{\text{int}}(t_1)\right)$ is the propagator relating to the big, non-interesting interaction $H_{\text{int}}(t)$ defining our interaction representation (typically the Hamiltonian of the rf pulse sequence).

The relatively simple formulas in Equations (1)–(3) have formed the basis for analytical evaluation of essentially all solid-state NMR experiments in the past three decades. This applies for the design and description of pulse sequences for decoupling of homo- and heteronuclear dipolar (or J) coupling interactions [1–4,8,19–21], selective recoupling of anisotropic dipolar coupling and chemical shielding interactions in MAS NMR [22,23], evaluation of solid-state NMR experiments for analysis of quadrupolar nuclei [24], etc. It has been more the rule than the exception that any new experiment or pulse sequence building block was characterized by its effective Hamiltonian. For recoupling experiments, it has been the purpose to avoid coherent averaging of anisotropic interactions by sample rotation, and as so the first-order expressions were relevant for the recoupled interactions (e.g. a specific dipole–dipole coupling), while higher-order terms were relevant for the interactions that should remain averaged (e.g. isotropic and anisotropic chemical shifts). For decoupling sequences, it has obviously been the aim to eliminate the "coupling" interaction to as high order as possible—each time revealing that the high-order terms that intuitively only describe marginal effects actually become exceedingly important—and spectrally very visible—when all lower-order terms have been suppressed.

This has created a need to facilitate calculation of high-order terms, which not only is complicated by the more complex formula for the integrant (cf. Equation (2)), but also by the need to keep track of the time-ordering of the multiple integrals. This may be quite demanding, in particular for pulse sequence containing many elements with differently modulated Hamiltonians. To serve this need we introduced the so-called semi-continuous Baker–Campbell–Hausdorff (scBCH) expansion [9]. Here the effective Hamiltonians calculated for each period using the Magnus expansion (Equation (2)) are used as static entries to the Baker–Campbell–Hausdorff expansion, which thereby acts as an ordering structure. The first three order coupling equations are expressed as

$$\bar{\bar{\tilde{H}}}^{(1)} = \frac{1}{\tau_c}\sum_{i=1}^{n}\tau_i\bar{\bar{\tilde{H}}}_i^{(1)} \quad (4a)$$

$$\bar{\bar{\tilde{H}}}^{(2)} = \frac{1}{\tau_c}\sum_{i=1}^{n}\tau_i\bar{\bar{\tilde{H}}}_i^{(2)} + \frac{1}{2i\tau_c}\sum_{i>j}^{n}\tau_i\tau_j\left[\bar{\bar{\tilde{H}}}_i^{(1)},\bar{\bar{\tilde{H}}}_j^{(1)}\right] \quad (4b)$$

$$\begin{aligned}\bar{\bar{\tilde{H}}}^{(3)} = {} & \frac{1}{\tau_c}\sum_{i=1}^{n}\tau_i\bar{\bar{\tilde{H}}}_i^{(3)} + \frac{1}{2i\tau_c}\sum_{i>j}^{n}\tau_i\tau_j\left(\left[\bar{\bar{\tilde{H}}}_i^{(1)},\bar{\bar{\tilde{H}}}_j^{(2)}\right]\right.\\ & \left.+\left[\bar{\bar{\tilde{H}}}_i^{(2)},\bar{\bar{\tilde{H}}}_j^{(1)}\right]\right) - \frac{1}{6\tau_c}\sum_{i>j>k}^{n}\tau_i\tau_j\tau_k\left(\left[\bar{\bar{\tilde{H}}}_i^{(1)},\left[\bar{\bar{\tilde{H}}}_j^{(1)},\bar{\bar{\tilde{H}}}_k^{(1)}\right]\right]\right.\\ & \left.+\left[\bar{\bar{\tilde{H}}}_k^{(1)},\left[\bar{\bar{\tilde{H}}}_j^{(1)},\bar{\bar{\tilde{H}}}_i^{(1)}\right]\right]\right) - \frac{1}{12\tau_c}\sum_{i>j>k}^{n}\\ & \times\left(\tau_{ii}^2\tau_j\left[\bar{\bar{\tilde{H}}}_i^{(1)},\left[\bar{\bar{\tilde{H}}}_i^{(1)},\bar{\bar{\tilde{H}}}_j^{(1)}\right]\right] + \tau_i\tau_j^2\left[\bar{\bar{\tilde{H}}}_i^{(1)},\left[\bar{\bar{\tilde{H}}}_j^{(1)},\bar{\bar{\tilde{H}}}_j^{(1)}\right]\right]\right),\end{aligned} \quad (4c)$$

which straightforwardly can be extended to formulas that apply for the terms just above a certain order m to which a "first-iteration" pulse sequence eliminates a given interaction (for details see Ref. [9]). For example, consider a sequence for which the basic element eliminates terms of order 1. If this element is concatenated with its reflection symmetric counterpart then the sequence eliminates all even order terms. This leaves us with coupling of third, fifth, and seventh order terms as direct sums similar to the third-order terms in Equation (4c).

With the aim of establishing more accurate—ideally exact—representations of effective Hamiltonians, we recently introduced the so-called Exact Effective Hamiltonian Theory (EEHT) [10,11]. EEHT exploits the highly celebrated spectral theorem or the Caley–Hamilton theorem to obtain a finite-series closed solution to the Baker–Campbell–Hausdorff problem. The basic idea is that the effective Hamiltonian reflecting the action of two entangled propagators may not only be represented by its infinite series expansion

$$-iH^{\text{eff}}\tau = \ln\left(\mathrm{e}^{iA}\mathrm{e}^{iB}\right) = \sum_{k=1}^{\infty}\frac{1}{k}X^k \quad (5)$$

with $X = 1 - e^{iA}e^{iB}$, but also as a finite series

$$-iH^{\text{eff}}\tau = \sum_{i=1}^{N}g_{i-1}X^{i-1}, \quad (6)$$

containing only N terms, where N is the matrix dimension of the Lie algebra (i.e. the number of energy levels in the spin system). Considering that essentially all EHT calculations have been performed on two-, three-, or four-level systems, it appears intuitively very attractive to obtain an exact description using only two, three, or four terms instead of an infinite series of ordered contributions for each of these cases. Obviously, the relevance of this statement depends on the derivation of the g expansion factors. For at two-level system, the g factors are related to the eigenvalues λ_i for the operator X as

$$mg_0 = -\lambda_2 \ln(1-\lambda_1) + \lambda_1 \ln(1-\lambda_2) \tag{7a}$$

$$mg_1 = \ln(1-\lambda_1) - \ln(1-\lambda_2) \tag{7b}$$

with $m = \lambda_1 - \lambda_2$. For a three-level system (e.g. a spin-1 case or the strong-coupling part of a two-spin-1/2 system) the g values are given by

$$\begin{aligned} mg_0 = {} & \left(\lambda_2^2\lambda_3 - \lambda_3^2\lambda_2\right) \ln(1-\lambda_1) + \left(\lambda_3^2\lambda_1 - \lambda_1^2\lambda_3\right) \\ & \times \ln(1-\lambda_2) + \left(\lambda_1^2\lambda_2 - \lambda_2^2\lambda_1\right) \ln(1-\lambda_3) \end{aligned} \tag{8a}$$

$$\begin{aligned} mg_1 = {} & \left(\lambda_3^2 - \lambda_2^2\right) \ln(1-\lambda_1) + \left(\lambda_1^2 - \lambda_3^2\right) \ln(1-\lambda_2) \\ & + \left(\lambda_2^2 - \lambda_1^2\right) \ln(1-\lambda_3) \end{aligned} \tag{8b}$$

$$\begin{aligned} mg_2 = {} & (\lambda_2 - \lambda_3) \ln(1-\lambda_1) + (\lambda_3 - \lambda_1) \ln(1-\lambda_2) \\ & + (\lambda_1 - \lambda_2) \ln(1-\lambda_3) \end{aligned} \tag{8c}$$

with $m = (\lambda_1 - \lambda_2)(\lambda_1 - \lambda_3)(\lambda_2 - \lambda_3)$ and the formula applying for the case of non-degenerate eigenvalues. Degenerate cases as well as four-level systems are covered by the more detailed descriptions in Refs. [10,11].

Without going into detail with the underlying theory, it is clear that the EEHT expansion in Equation (6), with the appropriate expansion coefficients may prove powerful for establishing exact expressions for entangled propagators in cases where the eigenvalues can be established analytically. This applies typically for 2–4 level systems, i.e. exactly the same area of action as the normal Magnus expansion based AHT. A few essential features should be mentioned: First, it is clear that the entanglements are not restricted to concatenation of two propagators although, obviously, the X operators become increasingly complicated. For the concatenation of n propagators

$$X = 1 - U_1 U_2 \cdots U_n \tag{9}$$

where $U_i = \mathrm{e}^{iH_i t_i}$ is the ith propagator relating to the Hamiltonian H_i and the time interval t_i. Second, being exact in nature, EEHT allows for the establishment of analytical insight about the effective Hamiltonian in the *normal rotating frame*, rather than in one, or often more, "ad-hoc-constructed" interaction frame(s) that enable fast convergence of an infinite series to the lower-order terms. It is obvious that this renders the description much simpler. In many cases far most of the complicating time-dependency of the Hamiltonians actually comes from the transformation into the interaction frame(s). Another important issue is that it may be practically impossible to find appropriate interaction frames, because it is a requirement that the frequency of the "big" interaction is orders of magnitude larger than the internal interactions. This may be complicated if several frames have to be used at the same time, or if the internal interactions are much stronger than the available external manipulations (which may be case, e.g. for quadrupolar nuclei, where internal interaction frequencies up to many MHz may be encountered). The ability to perform the analytical evaluations in the normal rotating frame may also facilitate direct comparison between analytical and numerical evaluations. Third, EEHT may also provide a useful means to obtain *ordered expressions* for high-order effective Hamiltonians. This may be obtained through a simple Taylor expansion

$$H^{\mathrm{eff}}(a + a_0) = \sum_{i=1}^{n} \frac{a^n}{n!} \left(\frac{\mathrm{d}^n}{\mathrm{d}a^n} H^{\mathrm{eff}}(a) \right)_{a_0} \tag{10}$$

of the EEHT-derived exact effective Hamiltonian in the relevant controlling variable (often the frequency of the undesired interaction scaled according to strength of the external field; in this the variation a away from its expansion point a_0) [10]. This "easy route" to high-order Hamiltonians may be useful in cases where an ordered expansion is needed for systematic design of pulse sequences to eliminate the most important components of non-desired interactions. Finally, we should note that the highly structured way of establishing the exact effective Hamiltonians and the ordered Taylor expansions may be taken into advantage by performing the difficult calculations [10] in symbolic mathematics programs such as Mathematica [25].

Numerical Tools

While analytical tools are extremely useful for evaluation of the overall performance of advanced pulse experiments and systematic design of these, it is often performed on simplified systems with respect to the number of spins and nuclear spin interactions (see Figure 1). Also issues like the simultaneous contribution from many molecules with different orientation relative to the external magnetic field, and thereby different anisotropic nuclear spin interactions, may be difficult to handle appropriately by analytical means. Such evaluations are typically left to experimental tests or to numerical simulations. Although the former obviously provides the answer from the spins themselves, the latter has the advantage that many "experiments" can be tested under different conditions without the need to produce many expensive compounds with different isotope labels and without using excessive spectrometer time.

Based on an increasing understanding of the underlying spin dynamics and easy/cheap access to powerful computers, the past decade has witnessed the appearance of numerous powerful simulation programs which in principle allow for exact calculation of advanced solid-state NMR experiments for large spin systems. These programs includes ANTIOPE [14], Gamma [15], SIMPSON [16], Blochlib [17], and SPINEVOLUTION [18], which—in particular the newer programs—exploit the most recent methods for efficient handling of crystallite orientation and time symmetries in rotating sample experiments [26–33] as described along with examples in recent reviews [34,35].

Among the simulation programs, more recent open-source program packages such as SIMPSON [16,34–39] have gained a very widespread popularity due to a very flexible scripting interface that allows the performance of advanced pulse sequence simulations with a programming effort similar to that used for programming the pulse sequence on the spectrometer. For example, using SIMPSON's simple Tcl interface [36,40], it is straightforward to implement pulse sequences (pulses, delays, etc.), external manipulations (rf irradiation, stationary external field, powder conditions, sample spinning, etc.), as well as the nuclear spin system to explore the performance of pulse sequences development by other means (e.g. using EHT) or for computer-assisted experiment design. The latter may be conducted using integrations of SIMSPON with MINUIT [41] non-linear optimization [36] or with optimal control theory [42–44] for experiment optimization [39].

To facilitate the establishment of realistic, large spin systems—primarily for biological solid-state NMR—we recently introduced the auxiliary program SIMMOL [45] that uses atomic coordinates in the PDB (Protein Data Bank) [46] format to generate representative tensorial parameters for proteins or fragments of these. This is obviously possible for the dipole–dipole coupling interactions that depend exclusively on the internuclear distance and the orientation of the internuclear vector, but it is actually possible also to predict the magnitude and orientation of chemical shielding tensors quite precisely based on empirical rules. For example, the backbone chemical shielding tensors have essentially the same magnitude and orientation relative to the peptide plane independently on the residue type, and for the sidechain tensors there are often empirical rules that enable orientation of the tensors relative to the nuclear bonds. In this manner it is possible to establish very reliable multiple-spin parameter sets for numerical evaluation of pulse sequences without the need for excessive work to establish, in particular, the tensor orientations by manual means. The combined used of SIMMOL and SIMPSON for systematic experiment design is promoted in Figure 1.

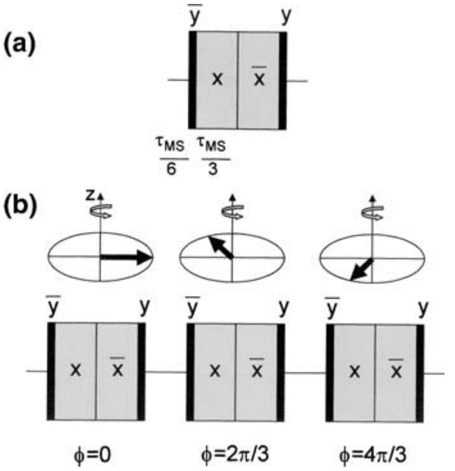

Fig. 2. Magic-sandwich (MS) (a) and high-order truncating MSHOT3 (b) pulse sequences for homonuclear dipolar decoupling in ^{1}H solid-state NMR spectroscopy. The pulse sequences are analyzed using EEHT under the assumption of ideal $(\pi/2)_{\pm y}$ bracketing pulses and that the pulses of duration $\tau_{MS}/3$ correspond to 2π rotations under influence of the dipolar coupling interaction (as through the free precession period of half duration).

Systematic Design of Solid-State NMR Experiments

To illustrate the use of the analytical and numerical tools described in the previous section, we will briefly review a couple of examples of their use for evaluation and design of solid-state NMR experiments. The first example concerns the usage of EEHT [10] to evaluate the high-order truncating MSHOT-3 pulse sequence [47] relative to its predecessor, the magic-sandwich (MS) pulse sequence [48], for homonuclear decoupling in ^{1}H solid-state NMR. The second-example illustrates the use of optical control theory in combination with SIMPSON numerical simulations for computer-automated design of optimal recoupling NMR experiments.

Example 1: One of the absolute driving forces for the analytical development of NMR originates from the wish to be able to do ^{1}H NMR spectroscopy on solid-samples. Considering the relative narrow range of 10 ppm or so for the isotropic chemicals shifts—amounting to 5 kHz on a 500 MHz spectrometer—this requires efficient ways to eliminate the overwhelming ^{1}H–^{1}H dipole–dipole couplings which may range up to more that 30 kHz. One of the pioneering sequences for homonuclear decoupling was the MS sequence [48] in Figure 2a, which can be analyzed using EEHT using the following steps [10]. (i) The propagators relevant for the various pulse sequence elements are established as

$$U_f = \mathrm{e}^{-i2a\sqrt{6}T_{2,0}},\ U_y = \mathrm{e}^{-i\pi(I_y+S_y)/2},$$
$$U_{\pm x} = \mathrm{e}^{-i\left[\pm 2\pi(I_x+S_x)+4a\sqrt{6}T_{2,0}\right]} \tag{11}$$

where f, y, and $\pm x$ denote propagators for free precession, the bracketing y-pulse (assumed ideal), and the $(2\pi)_{\pm x}$ pulses, respectively, while $T_{2,0} = (2I_zS_z - I_xS_x - I_yS_y)/\sqrt{6}$ and $a = \pi\omega_D/(2\omega_{\mathrm{rf}})$ with ω_D being the dipolar coupling frequency and ω_{rf} the rf field strength (both in angular frequency units). (ii) The X operator is defined as

$$X = 1 - U_f U_y^{+} U_x U_{-x} U_y U_f, \tag{12}$$

for which (iii) the eigenvalues

$$\lambda_1 = 0,$$
$$\lambda_{2,3} = \frac{18a^2s_\alpha^2 \mp 3\sqrt{2}as_\alpha\sqrt{-9a^2-8\pi^2-9a^2c_{2\alpha}}}{\alpha^2} \tag{13}$$

can be found with $s_\alpha = \sin(\alpha)$, $c_\alpha = \cos(\alpha)$, and $\alpha = \sqrt{9a^2+4\pi^2}$. Using Equations (6) and (8) (description in $su(3)$) and decomposition into irreducible spherical tensor operators [10], this leads (iv) to the exact effective Hamiltonian ($\tau_{\mathrm{MS}} = 6\pi/\omega_{\mathrm{rf}}$)

$$-iH^{\mathrm{eff}}\tau_{\mathrm{MS}} = b_{2,2}^{\mathrm{MS}}T_{2,2} + b_{2,-2}^{\mathrm{MS}}T_{2,.2}, \tag{14}$$

with $T_{2,\pm2} = \frac{1}{2}I_1^{\pm}I_2^{\pm}$ and

$$b_{2,2}^{\mathrm{MS}} = \left(-b_{2,-2}^{\mathrm{MS}}\right)^*$$
$$= \frac{-\sqrt{2}a\alpha^2[\ln(1-\lambda_2)-\ln(1-\lambda_3)]\,s_\alpha\,(i\alpha c_\alpha + 2\pi s_\alpha)}{s_\alpha a\alpha^2\sqrt{-9a^2-8\pi^2-9a^2c_{2\alpha}}}, \tag{15}$$

$$\approx \frac{-27ia^3}{2\pi^2} - \frac{243\,(-3i+4\pi)\,a^5}{32\pi^4} + \frac{729\,[-15i+4\,(9+4i\pi)\,\pi]\,a^7}{256\pi^6} + \mathrm{O}(a^9), \tag{16}$$

where the approximation in Equation (16) was derived by (v) Taylor expansion (Equation (10)) of the exact expression in Equation (15) around $a_0 = 0$, resulting in an ordered expression identical to the one obtained using the scBCH expansion [9,47].

The exact effective Hamiltonian reveals that the residual dipolar terms for the MS sequence is of the type $T_{2,\pm2}$—which immediately indicates that an improved dipolar coupling suppression may be obtained by concatenating z-rotated elements, such as accomplished for by three elements mutually phase-shifted by $2\pi/3$ in the MSHOT-3 pulse sequence [47] in Figure 2b. MSHOT-3 is characterized by the effective Hamiltonian ($\tau_{\mathrm{MSHOT3}} = 3\tau_{\mathrm{MS}}$)

$$-iH^{\mathrm{eff}}\tau_{\mathrm{MSHOT3}} = b_{1,0}^{\mathrm{MSHOT3}}T_{1,0} + b_{2,0}^{\mathrm{MSHOT3}}T_{2,0} + b_{2,2}^{\mathrm{MSHOT3}}T_{2,2} + b_{2,-2}^{\mathrm{MSHOT3}}T_{2,2} \tag{17}$$

with the Taylor expanded coefficients

$$b_{1,0}^{\mathrm{MSHOT3}} \approx \frac{i729\sqrt{3}a^6}{32\pi^4} - \frac{19683i\sqrt{3}a^8}{256\pi^6} + \mathrm{O}(a^{10}),$$
$$b_{2,0}^{\mathrm{MSHOT3}} \approx \mathrm{O}(a^{10}) \quad b_{2,2}^{\mathrm{MSHOT3}} = \left(-b_{2,2}^{\mathrm{MSHOT3}}\right)^*$$
$$\approx \frac{19683\left(i+\sqrt{3}\right)a^9}{64\pi^6} + \mathrm{O}(a^{10}) \tag{18}$$

showing that the dipolar suppression is improved by three orders in the effective Hamiltonian expansion on going from MS to MSHOT3.

Example 2: While analytical tools like EHT and advanced variants are considered indispensable in experiment design, it has been much less typical to use numerical simulations in the *first phase* of experiment design. Indeed, numerical simulations have been used, but typical in the *second phase* as a more critical evaluator after the experiments have been designed by other means. However, in few cases non-linear optimization has been used, e.g. for design of experiments for TOSS spinning sideband suppression [49], homonuclear dipolar decoupling experiments [50,51], and adiabatic-passage dipolar recoupling [34,52]. Probably one of the reasons for not using non-linear optimization for designing solid-state NMR experiments from scratch is that the number of free variables required for non-constrained optimizations typically is very large, implying that non-linear optimization is very slow, and prone to identification of local extrema rather than global ones. To remedy this problem, we recently explored the use of optimal control theory [44] in combination with SIMPSON as a route to explore how efficient pulse sequences actually can be made if the degrees of freedom are opened up radically, *and* as a means to create optimal pulse sequences numerically in an automated fashion. The idea is to provide the program with information on the spin system, the initial and desired target spin operators, information on the external spinning and rf conditions (including rf inhomogeneity, maximum available/desired rf field strengths, etc.), and a desired length

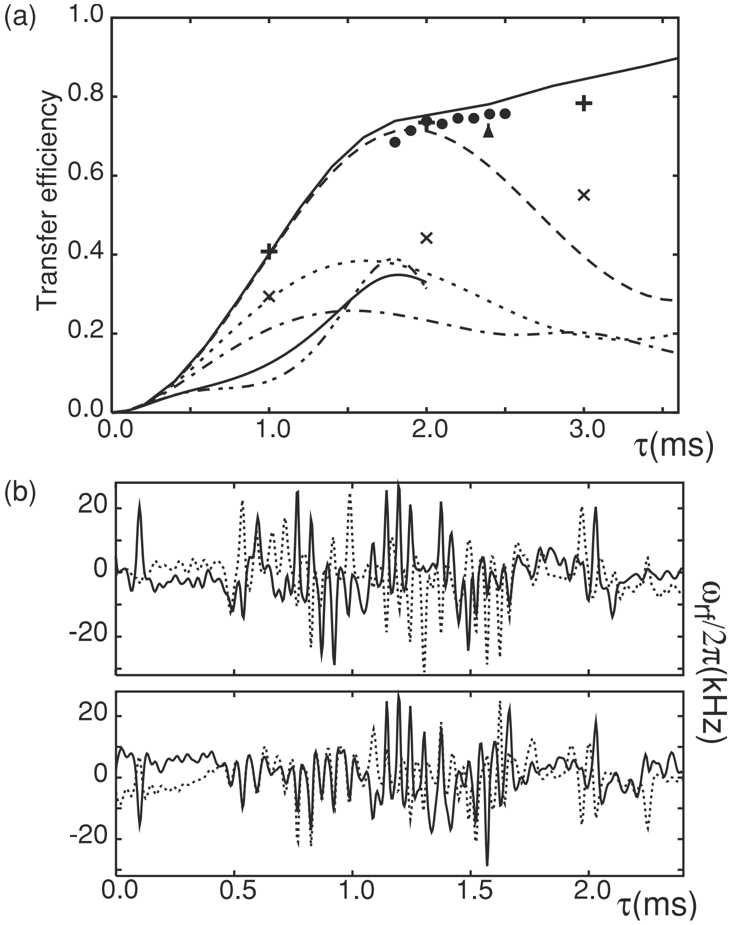

Fig. 3. (A) Numerical evalution of ^{15}N $\rightarrow ^{13}$C$_\alpha$ coherence transfer in glycine calculated for different recoupling experiments under conditions of homogeneous and inhomogeneous rf fields: DCP (homogeneous rf: —; 5% Lorentzian rf inhomogeneity: ····, 10% Lorentzian rf inhomogeneity: · — ·—), ramped DCP (homogeneous rf: -·· ·-, 5% Lorentzian rf inhomogeneity: -···), adiabatic CP (homogeneous rf: +, 5% Lorentzian rf inhomogeneity: x), and optimal control ^{OC}DCP (homogeneous rf: solid line, 5% Lorentzian rf inhomogeneity: ● ● ●). (b) ^{15}N (upper) and ^{13}C rf field amplitudes (x-phase: solid line, y-phase: dotted line) for the 2.4 ms ^{OC}DCP experiment marked with arrow in (a). Reproduced from Ref. [39] with permission.

of the experiment, and then let it calculate the optimal pulse sequence.

With reference to our presentation in Ref. [39], Figure 3 illustrates the outcome of an optimal control analysis and design strategy to create improved heteronuclear dipolar recoupling experiments for ^{15}N → ^{13}C$_\alpha$ coherence transfer in MAS NMR of solid proteins. The upper panel compares numerically the transfer efficiencies for DCP [53], ramped DCP [54], and adiabatic variants [55] of DCP subject to homogeneous and different inhomogeneous rf field conditions. Overall it is quite clear that these traditional schemes are quite sensitive to rf inhomogeneity, a problem that may be solved by taking these effects into account in optimal control SIMPSON design of improved pulse sequence. In Figure 3a, the solid-curve describes the transfer efficiency of optimal control sequences under conditions of homogeneous rf fields, while the black dots (essentially providing the same efficiency) reflect sequences optimized under conditions of a 5% Lorentzian (or a 9.2% Gaussian) rf inhomogenity profile on both spins (identical on the two channels). Figure 3B illustrates the ^{15}N (upper) and ^{13}C (lower) rf pulse sequences corresponding to a mixing time of 2.4 ms (indicated by arrow in Figure 3a). Experimentally this pulse sequence provides 53% higher transfer efficiency than a DCP experiment [39], despite the fact that the latter experiment uses significantly stronger rf fields (25 and 35 kHz on the two channels, while the optimal control ^{OC}DCP sequences have root-mean-square average rf field strengths of 10.4 and 9.5 kHz on the two channels). The development of low-power recoupling experiments is regarded very important considering that many of the current recoupling sequences are technically difficult to perform with ^{1}H decoupling under high-speed spinning conditions due to very high demands on the rf field strength and in addition strong rf may heat, and thereby potentially destroy, the sample.

Conclusions

In conclusion, we have briefly reviewed some of the most powerful tools used for systematic design of solid-state NMR experiments: EHT with some recent twists toward high-order or exact formulation and numerical simulations in terms of the SIMPSON and SIMMOL software packages. Both tools are quite universal and are fine complements to intuition and inspiration from other sources in a procedure for systematic design of optimal experiments.

Homonuclear Shift-Correlation Experiment in Solids

K. Takegoshi

Department of Chemistry, Graduate School of Science, Kyoto University, Kyoto 606-8502, Japan

In solution-state NMR, homonuclear shift correlation experiments, such as COSY and INADEQUATE, have successfully been used for signal assignment. In these experiments, correlation between spins is established via through-bond J couplings, so that each cross peak represents corresponding chemical bonding. Similar J-correlation experiments can also be applicable in solids. Due to the low resolution of ^{1}H resonances in the solid-state NMR, however, we use other spin-1/2 nuclei such as ^{13}C and ^{15}N, whose high resolution observation is capable in solids by the combined use of magic-angle spinning (MAS) and ^{1}H decoupling. Since these isotopes are rare in natural abundance, homonuclear shift-correlation experiment in solids requires a uniformly ^{13}C or ^{15}N-labeled sample. Hereafter, we examine experiments on ^{13}C spins, but most results can also be applied to other rare spin-1/2 nuclei (^{15}N, ^{19}Si, etc). Figure 1a shows a COSY pulse sequence in solids; instead of a single 90° pulse used in solution NMR, cross polarization is applied for excitation. Figure 1b shows a ^{13}C-COSY contour spectrum of [u-^{13}C,^{15}N] glycilisoleucine ([u-^{13}C,^{15}N] GlyIle).[1] The straight lines indicate ^{13}C–^{13}C J connectivity. As exemplified by this, it is straightforward to implement J-based sequences in solid NMR. However, ^{13}C-COSY and/or INADEQUATE have not been popular so far. One of the reasons may be ascribed to the size of the J interaction being much smaller than those of the other spin interactions. To observe small ^{13}C–^{13}C J splitting of a few 10 Hz, line broadening due to ^{13}C–^{13}C dipolar coupling should be removed by fast MAS together with the removal of ^{13}C–^{1}H dipolar broadening by efficient ^{1}H decoupling. Further, the sample-rotation angle should precisely be adjusted to the magic angle to get rid of broadening due to the anisotropic chemical-shift interaction.

^{13}C–^{13}C shift-correlation experiments can also be done by using ^{13}C–^{13}C dipolar interactions. In contrast to isotropic J coupling employed in COSY and INADEQUATE, which is not affected by MAS, dipolar couplings among ^{13}C spins are averaged by MAS. Hence, a certain pulse sequence should be applied to recover ^{13}C–^{13}C dipolar couplings under MAS. Further, for a such sequence being useful for signal assignment, it should be able to recouple ^{13}C spins non-selectively (broadbandly). A number of sequences for broadband ^{13}C–^{13}C dipolar recoupling under MAS have been developed, to name a few examples, DRAMA[2], RFDR[3] and C7[4]. These sequences apply rotation-synchronous ^{13}C rf pulses to interrupt the averaging of the ^{13}C–^{13}C dipolar interactions by MAS, and are adopted in the mixing time of a 2D homonuclear shift-correlation experiment in solids (Figure 2). To remove ^{13}C–^{1}H dipolar interactions, these recoupling sequences require ^{1}H decoupling during the mixing time. In order to avoid recoupling of the ^{13}C–^{1}H dipolar interactions during ^{13}C rf pulses, the ^{1}H rf strength much larger than that of the ^{13}C rf (more than three times for a ^{13}C π pulse)[5] is required in the mixing time. Further, precise synchronization of the pulses and the rotation is necessary, which tends to limit the MAS speed and thus leads to imperfect removal of ^{13}C–^{13}C dipolar broadening in t_1 and t_2.

^{13}C signal assignment can be done by examining ^{13}C–^{13}C cross peaks at a short mixing time, where polarization transfer by ^{13}C–^{13}C dipolar interactions would occur mostly for directly bonded ^{13}C–^{13}C pairs. Although for a longer mixing time, long-range distance correlation may be observed. In broadband dipolar recoupling experiments, however, such long-range correlation tends to be lost due to the so-called dipolar truncation effect, that is, the strong dipolar coupling for a pair of adjacent ^{13}C–^{13}C spins tends to suppress weaker couplings between a ^{13}C spin in the pair and remote ^{13}C spins.[6–8] Figure 3a and b show ^{13}C–^{13}C 2D homonuclear correlation spectra observed for uniformly ^{13}C/^{15}N-labeled N-acetyl-Pro-Gly-Phe ([u-^{13}C,^{15}N] Ac-Pro-Gly-Phe) by applying RFDR and C7, respectively, during the mixing time (τ) of 10 ms. Examination of the observed 2D RFDR and C7 spectra indicates that the dipolar truncation is most prominent for the C_α and $C = O$ carbons of Gly (Figure 4a and b). This can be attributed to isolation of the two ^{13}C spins due to absence of side-chain carbons in Gly; the dipolar coupling between the two ^{13}C spins is much stronger than the dipolar couplings between one of them and outer ^{13}C spins. The dipolar truncation effects are appreciable because these sequences recover ^{13}C–^{13}C dipolar couplings uniformly. In other words, a ^{13}C–^{13}C recoupling sequence that can avoid dipolar truncation should recouple ^{13}C–^{13}C dipolar couplings non-uniformly.

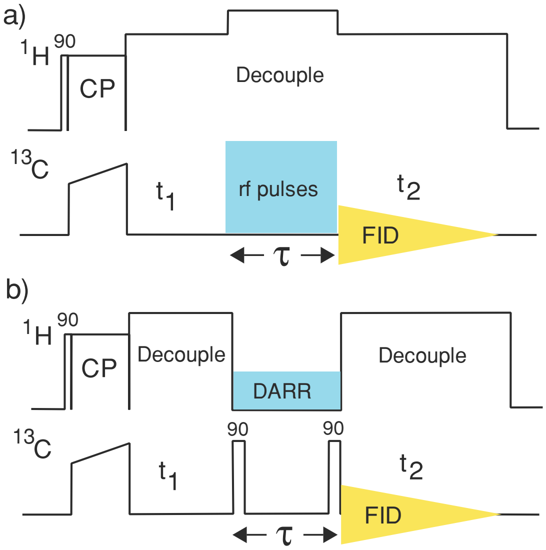

Fig. 2. (a) Pulse sequence for a 2D ^{13}C–^{13}C shift-correlation experiment in solids with rotor-synchronized ^{13}C pulses for ^{13}C broadband recoupling applied in the mixing time (τ) together with ^{1}H decoupling. To avoid ^{13}C–^{1}H recoupling, ^{1}H decoupling intensity in the mixing time is increased. (b) Pulse sequence for a 2D ^{13}C–^{13}C shift-correlation experiment in solids using DARR. In DARR, no ^{13}C rf pulses are applied in the mixing time but ^{1}H spins are irradiated to recover ^{13}C–^{1}H dipolar interactions.

Figure 3c shows a ^{13}C–^{13}C 2D homonuclear correlation spectrum observed for [u-^{13}C,^{15}N] Ac-Pro-Gly-Phe by applying DARR (^{13}C–^{1}H dipolar-assisted rotational resonance)[9,10] during the mixing time of 200 ms. In DARR, broadband recoupling is achieved by ^{13}C–^{13}C spectral overlap realized by the ^{13}C–^{1}H dipolar interaction recovered by suitable rf irradiation on ^{1}H, for example, ^{1}H irradiation with the intensity ν_1 satisfying the rotary-resonance condition $\nu_1 = n\nu_R (n = 1$ or $2)$,[11] where ν_R is the MAS spinning frequency (Figure 2b). For a pair of a carbonyl or an aromatic carbon and an aliphatic carbon, spectral overlap can be achieved between one of the spinning sidebands of the former ^{13}C resonance and the ^{13}C–^{13}H dipolar powder pattern of the latter (Figure 5a). On the other hand, for a pair of spins with a small chemical shift difference, the two center bands are overlapped with each other due to ^{13}C–^{1}H dipolar broadening (Figures 5b and c). These spectral overlaps allow rotational resonance recoupling, and therefore, facile polarization transfer under MAS,[10] and broadband recoupling is thus achieved. On the other hand, the partial spectral overlap causes orientationally selective recoupling, that is, not all ^{13}C–^{13}C pairs recouple. To sum up, DARR recouples ^{13}C–^{13}C dipolar interactions broadbandly but non-uniformly. This unique feature makes it possible to suppress the dipolar truncation effects as shown by the appearance of many cross peaks in the cross-section spectrum (Figure 4c) of the ^{13}C–^{13}C 2D DARR spectrum (Figure 3c) for the C$_\alpha$ carbon of Gly. DARR thus has desirable feature for signal assignment, that is, recoupling occurs broadbandly without significant dipolar truncation. In fact, more than half of the amino acid side chains of [u-^{13}C,^{15}N] ubiquitin were assigned by DARR with a mixing time of 20 ms.[12] Crocker *et al.* applied DARR to rhodopsin and showed that DARR cross-peak intensities reflect the corresponding C–C distances between tyrosine and retinal carbons.[13] These studies indicate that DARR can recouple ^{13}C–^{13}C dipolar couplings broadbandly without appreciable dipolar truncation effects even though the sample is extensively ^{13}C labeled.

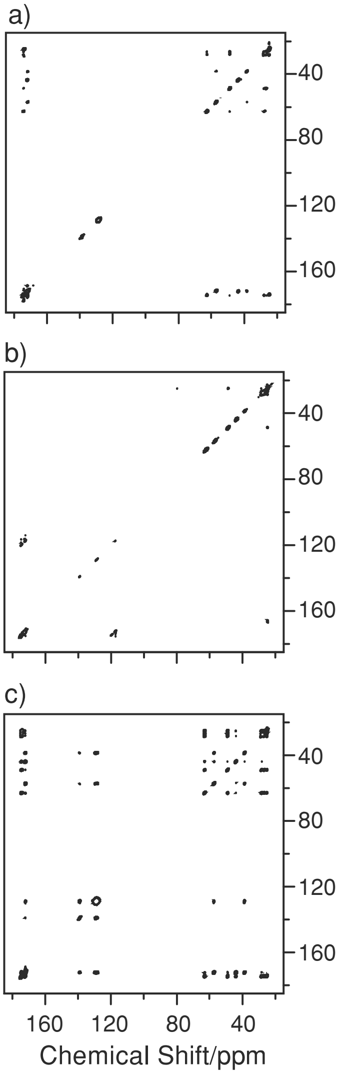

Fig. 3. Contour plots of ^{13}C–^{13}C 2D polarization-transfer spectra of [u-^{13}C,^{15}N] Ac-Pro-Gly-Phe. To reduce the effects of intermolecular couplings, the [u-^{13}C,^{15}N] Ac-Pro-Gly-Phe sample was diluted ten times with the natural abundance peptide in deionized water. The polarization transfer was realized by RFDR during the mixing time (τ) of 10 ms (a), by C7 with $\tau = 10$ ms (b), and by DARR with $\tau = 200$ ms (c). The contour line is plotted at 2.5% of the maximum intensity. The MAS spinning frequency was 20 kHz for (a and c) and 5.5 kHz for (b). The NMR experiments were performed on a Chemagnetics CMX-400 spectrometer operating at 100.7 MHz for ^{13}C.

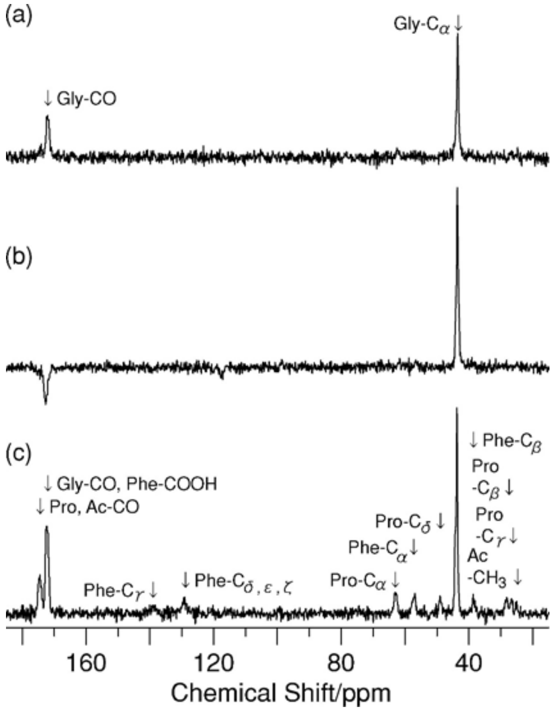

Fig. 4. Cross-sections at the C_α peak of Gly in the ^{13}C–^{13}C 2D polarization-transfer spectra (Figure 2) of [u-^{13}C,^{15}N] Ac-Pro-Gly-Phe. The polarization transfer was performed by using RFDR with $\tau = 10$ ms (a), C7 with $\tau = 10$ ms (b), and DARR with $\tau = 200$ ms (c). The inverted phase of the cross-peak by C7 is due to the double-quantum term in the recoupling Hamiltonian.[4]

Since the ^{13}C–^{1}H recoupling in DARR experiment is employed not for observing ^{13}C–^{1}H dipolar powder patterns but just for spectral overlap, it is not necessary to optimize the ^{13}C–^{1}H recoupling as long as line broadening necessary for spectral overlap is achieved. To show this more explicitly, 1D ^{13}C–^{13}C polarization-transfer NMR experiments of *N*-acetyl[1,2-^{13}C,^{15}N] DL-valine under ^{1}H CW irradiation at various rf strengths (ν_1) were done at $\nu_R = 15$ kHz, and the observed initial transfer rates *k* between ^{13}C$=$O and ^{13}C$_\alpha$ were plotted in Figure 6.[10] One broad maximum is found at the $n = 1$ rotary-resonance condition ($\nu_1 = \nu_R = 15$ kHz), which is attributed to the first-order DARR, and two other maxima at 25 and 35 kHz are deviated by $\pm \sim 5$ kHz from the $n = 2$ rotary-resonance condition ($\nu_1 = 2\nu_R = 30$ kHz). The broad maximum around the $n = 1$ rotary-resonance condition indicates that slight misadjustment of the ^{1}H rf intensity or the spinning frequency is not crucial for the first-order DARR by the $n = 1$ rotational-resonance irradiation. Phrased alternatively, DARR is tolerable to rf inhomogeneity. The observed tolerance would alleviate precise settings of experimental conditions often required for the other ^{13}C–^{13}C broadband recoupling experiments. On the other hand, the $n = 2$ rotary-resonance condition is not a good choice for DARR: the optimal irradiation condition deviates significantly from the exact DARR condition (Figure 6), which was attributed to the particular ^{13}C–^{1}H dipolar broadening lineshape of the C_α carbon.[10]

In this section, it was shown that DARR has the following desirable features for homonuclear shift-correlation experiment: (1) broadband recoupling, (2) less restriction for the spinning speed and stability, (3) low rf-power requirement, (4) tolerance to rf inhomogeneity, and (5) a long mixing time comparable to the spin-lattice relaxation time of ^{13}C. Further, it was indicated that the cross-peak intensity and the internuclear distance are well correlated with each other.[10] Similar correlation has also been observed in the nuclear Overhauser polarization (NOP) experiments using DARR in [u-^{13}C,^{15}N] GlyIle[14] we found that the polarization-transfer rate from the polarized $^{13}CH_3$ spin to another ^{13}C spin correlates well with the ^{13}C–^{13}C distance, thus leading to possibility of broadband 2D DARR recoupling experiments to determine ^{13}C–^{13}C distances in a multiply ^{13}C-labeled sample.

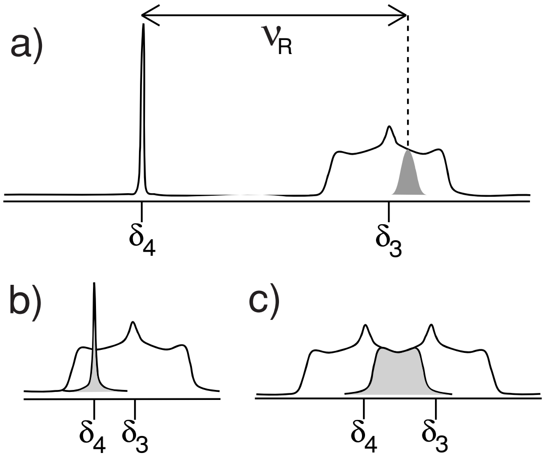

Fig. 5. Schematic ^{13}C MAS spectra of two ^{13}C spins under ^{13}C–^{1}H recoupling, showing various types of spectral overlap necessary for energy conservation in ^{13}C–^{13}C polarization transfer. Spectrum (a) represents two resonances of ^{13}CH at δ_1 and $^{13}C{=}O$ at δ_2. The hatched peak denotes one of the spinning sidebands of the $^{13}C{=}O$ peak, being overlapped with the recovered ^{13}C–^{1}H dipolar powder pattern of the ^{13}CH resonance. Spectrum (b) shows spectral overlap for a pair of spins whose chemical shift difference is smaller than the ^{13}C–^{1}H dipolar broadening. Spectrum (c) shows the case when spectral overlap occurs between two ^{13}C–^{1}H dipolar powder patterns.

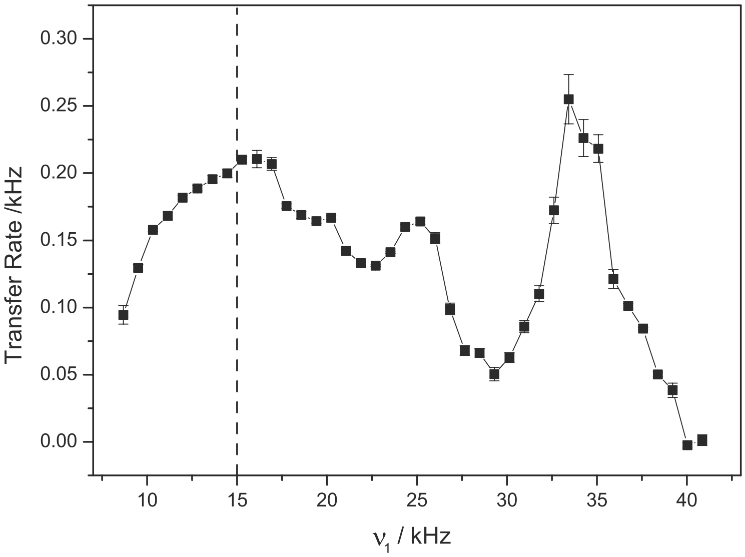

Fig. 6. Dependence of the polarization-transfer rate between $^{13}C{=}O$ and $^{13}C_\alpha$ of *N*-acetyl[1, 2-^{13}C, ^{13}N] DL-valine on the ^{1}H rf-field intensity ν_1 at $\nu_R = 15$ kHz. The rates were deduced by fitting the initial decay in the polarization-transfer curves for the difference of the magnetizations of the two carbons to a single exponential function. The line is drawn for eye guidance. The vertical dotted line indicates the position of the rotary-resonance condition.

Two-Dimensional ^{17}O Multiple-Quantum Magic-Angle Spinning NMR of Organic Solids

Gang Wu
Department of Chemistry, Queen's University, Kingston, Ontario, Canada K7L 3N6

Introduction

Solid-state nuclear magnetic resonance (SSNMR) spectroscopy has become an important technique for studying molecular structure and dynamics of chemical and biological systems. Most successful SSNMR studies have been based on observation of magnetically dilute spin-1/2 nuclei such as ^{13}C, ^{15}N, ^{29}Si, and ^{31}P, etc. Although oxygen is ubiquitous in organic and biological molecules, SSNMR studies for ^{17}O (the only NMR-active oxygen isotope) are far less common [1–4]. The scarcity of solid-state ^{17}O NMR studies arises from the fact that ^{17}O has a very low natural abundance (0.037%) and a quadrupolar nucleus (spin-5/2) with a sizable nuclear electric quadrupole moment ($eQ = -2.558$ fm^2). The major obstacle of obtaining SSNMR spectra for quadrupolar nuclei such as ^{17}O is the large size of nuclear quadrupole interactions (typically of the order of 10^6 Hz). This is because these large quadrupole interactions make it difficult to record SSNMR spectra with sufficient spectral resolution in order to resolve chemically or crystallographically different sites.

Solid-state ^{17}O NMR studies of organic compounds were pioneered by several research groups in the late 1980s and the early 1990s. In particular, Fiat and coworkers attempted to record solid-state ^{17}O NMR signals for crystalline amino acids [5]. Oldfield and coworkers applied solid-state ^{17}O NMR techniques to study hemoproteins and model compounds [6]. Ando and coworkers used solid-state ^{17}O NMR to examine hydrogen bonding interactions in polypeptides [7]. These early solid-state ^{17}O NMR studies were all based on a common technique known as the magic-angle spinning (MAS). As high magnetic fields are becoming available, a considerable acceleration has occurred in the past several years in solid-state ^{17}O NMR studies of organic and biological compounds [8–24].

One major limitation of the conventional MAS-based ^{17}O NMR studies is that spectral analyses were based exclusively on observation of "low-resolution" SSNMR spectra. This has made it very difficult to study chemical systems with more than one type of oxygen atoms. The intrinsic difficulty of obtaining high-resolution NMR spectra for ^{17}O arises from the fact that the second-order quadrupole interaction cannot be completely averaged by the traditional MAS technique. Although SSNMR techniques such as dynamic angle spinning (DAS) [25] and double rotation (DOR) [26] were developed for achieving high-resolution for half-integer quadrupolar nuclei including ^{17}O, these techniques are difficult to apply to organic compounds for various reasons. In 1995, Frydman and Harwood [27] introduced a new approach, known as the multiple-quantum magic-angle spinning (MQMAS) method, for completely averaging second-order quadrupole interactions. This new technique immediately attracted considerable attention because it can be readily implemented on most commercial NMR spectrometers. The first ^{17}O MQMAS NMR study was reported by Wu *et al.* [28]. The first ^{17}O MQMAS NMR study for organic compounds was demonstrated by Wu and Dong [29]. Rovnyak *et al.* recorded a ^{17}O MQMAS spectrum of L-asparagine monohydrate using nonlinear sampling [30]. Recently, Lemaitre *et al.* reported a ^{17}O MQMAS spectrum for monosodium L-glutamate [31]. Although the current number of ^{17}O MQMAS studies for organic compounds is still small, wider applications of the technique are anticipated as research interest in using solid-state ^{17}O NMR as a new probe for organic and biological systems continues to grow. Because of space limitation, this chapter will provide only a brief account on several practical aspects of ^{17}O MQMAS experiments.

Pulse Sequence, Data Processing, and Spectral Analysis

For a spin-5/2 nucleus, there are two possible symmetrical MQ coherences: triple-quantum (3Q) and quintuple-quantum (5Q) coherences. In general, it is much more difficult to excite a 5Q coherence than a 3Q coherence. Thus we here focus on the ^{17}O 3QMAS experiment. Figure 1 shows the three-pulse z-filter sequence [32] used for recording ^{17}O 3QMAS NMR spectra. The sequence utilizes the first pulse ($P1$) to excite the required symmetrical 3Q coherence. During the t_1 period, the dephasing of the 3Q coherence, $\nu^{(2)}_{\text{aniso}}(+\frac{3}{2}, -\frac{3}{2})$, is due to the second-order

Graham A. Webb (ed.), Modern Magnetic Resonance, 695–701.

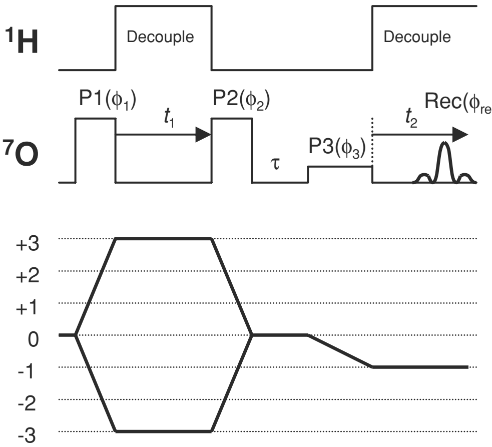

Fig. 1. The three-pulse z-filter sequence used in the ^{17}O 3QMAS experiment. The 24-step phase cycling scheme is: $\phi 1 = (0^\circ)$, $\phi 2 = (0^\circ, 60^\circ, 120^\circ, 180^\circ, 240^\circ, 300^\circ)$, $\phi 3 = (0^\circ, 180^\circ, 0^\circ, 180^\circ, 0^\circ, 180^\circ, 180^\circ, 0^\circ, 180^\circ, 0^\circ, 180^\circ, 0^\circ, 90^\circ, 270^\circ, 90^\circ, 270^\circ, 90^\circ, 270^\circ, 270^\circ, 90^\circ, 270^\circ, 90^\circ, 270^\circ, 90^\circ)$, and $\phi 4 = (0^\circ, 0^\circ, 0^\circ, 0^\circ, 0^\circ, 0^\circ, 180^\circ, 180^\circ, 180^\circ, 180^\circ, 180^\circ, 180^\circ, 90^\circ, 90^\circ, 90^\circ, 90^\circ, 90^\circ, 90^\circ, 270^\circ, 270^\circ, 270^\circ, 270^\circ, 270^\circ, 270^\circ)$. A typical set of experimental parameters are given as follows: $P1 = 5.5$ μs (at $\omega_1/2\pi = 90$ kHz), $\tau = 20$ μs (or $= \tau_r$), $P2 = 2.0$ μs (at $\omega_1/2\pi = 90$ kHz), $P3 = 27$ μs (at $\omega_1/2\pi = 3$ kHz).

quadrupole interaction. The second pulse ($P2$) converts the 3Q coherence into a Zeeman order. The delay, τ, is used to diphase the remaining transverse components (a z-filter). The third pulse ($P3$) is a selective 90° pulse for the central transition and converts the Zeeman order to the central transition coherence for detection. During the detection period, t_2, the dephasing of the CT coherence is also due to the second-order quadrupole interaction, $\nu^{(2)}_{\text{aniso}}(+\frac{1}{2}, -\frac{1}{2})$. Since $\nu^{(2)}_{\text{aniso}}(+\frac{3}{2}, -\frac{3}{2})$ and $\nu^{(2)}_{\text{aniso}}(+\frac{1}{2}, -\frac{1}{2})$ are related by a scaling factor, it is possible that the diphase of the 3Q coherence during t_1 can be reversed and refocused during the t_2 period for all crystallites. Because the coherence transfer pathway from the 3Q coherence to Zeeman order is symmetric, a pure cosine modulation from t_1 is achieved in the signal, $S_x(t_1, t_2)$. To construct a hypercomplex data set for generating pure-phase 2D spectra [33], one needs to repeat the 3QMAS experiment with a 30° phase shift for the $P1$ pulse so that a pure sine-modulated signal, $S_y(t_1, t_2)$, can be obtained. In the MQMAS experiment, because the time-domain echo occurs at $t_2 = kt_1$ (for ^{17}O 3QMAS, $k = 19/12$), the 2D frequency signal (lineshape) would appear tilted if a conventional double Fourier transformation is directly applied to the 2D time-domain signal. To obtain a 2D MQMAS spectrum where an isotropic spectrum appears on the F_1 axis, a shearing transformation is used between the two Fourier transformations [34]. We define the 3Q evolution time as t_1 and label the isotropic dimension, F_1, in frequency units (hertz). Using the convention suggested by Man [35], we can describe the peak positions along the isotropic dimension of a 3QMAS spectrum by

$$\nu^{\text{3QMAS}}_{\text{iso}} = -\frac{17}{12}\nu^{\text{CS}}_{\text{iso}} + \frac{5}{6}\nu^{(2)}_{\text{iso}} \tag{1}$$

where $\nu^{\text{CS}}_{\text{iso}}$ is the frequency contribution from the chemical shift and $\nu^{(2)}_{\text{iso}}$ is the isotropic second-order quadrupole shift defined as:

$$\nu^{(2)}_{\text{iso}} = -\frac{1}{500}\left(3 + \eta_Q^2\right)\frac{C_Q^2}{\nu_{\text{L}}} \tag{2}$$

In the above equation, C_Q is the nuclear quadrupole coupling constant ($C_Q = e^2qQ/h$), η_Q is the quadrupole asymmetry parameter, and ν_{L} is the ^{17}O Larmor frequency.

In the discussion that follows, we use crystalline [2,4–$^{17}O_2$]uracil as an example to illustrate MQMAS spectral analysis. Uracil is one of the common nucleic acid bases. The two oxygen atoms in the pyrimidine ring are chemically different: O_2 is related to a urea functional group and O_4 is similar to an amide oxygen. The crystal structure of uracil indicates that O_2 and O_4 also have quite different hydrogen bonding environment [36]. In particular, O_4 is involved in two nearly linear C=O$\cdots$H–N hydrogen bonds in a Y-shape fashion, meanwhile O_2 is free of any direct hydrogen bonding interaction. Figure 2 shows ^{17}O MAS and 3QMAS NMR spectra obtained for crystalline [2,4–$^{17}O_2$]uracil at 11.75 T. Because there are two oxygen sites in uracil, the 1D ^{17}O MAS spectrum exhibits a complex lineshape. It is not always possible to analyze such a lineshape without additional information. In comparison, the ^{17}O 3QMAS spectrum for [2,4–$^{17}O_2$]uracil shows clearly two isotropic peaks. As indicated in Figure 2, each isotropic peak in the F_1 dimension is related to a sub-spectrum along the F_2 dimension, from which δ_{iso}, C_Q, and η_Q can be estimated. However, it should be emphasized that, because F_2 sub-spectra often exhibit lineshape distortion and do not contain quantitative information about site population, they are usually used only as a starting point in the simulations of 1D MAS spectra. Final NMR parameter extraction is usually achieved by comparing spectral features (peaks and shoulders) in experimental and simulated 1D MAS spectra. Such a combined analysis of the 2D 3QMAS and 1D MAS spectra for crystalline uracil yielded the following parameters: O_2, $\delta_{\text{iso}} = 240 \pm 5$ ppm, $C_Q = 7.62 \pm 0.02$ MHz, $\eta_Q = 0.50 \pm 0.01$; O_4, $\delta_{\text{iso}} = 275 \pm 5$ ppm, $C_Q = 7.85 \pm 0.02$ MHz, $\eta_Q = 0.55 \pm 0.01$. The calculated ^{17}O MAS spectra and corresponding sub-spectra are also shown in Figure 2.

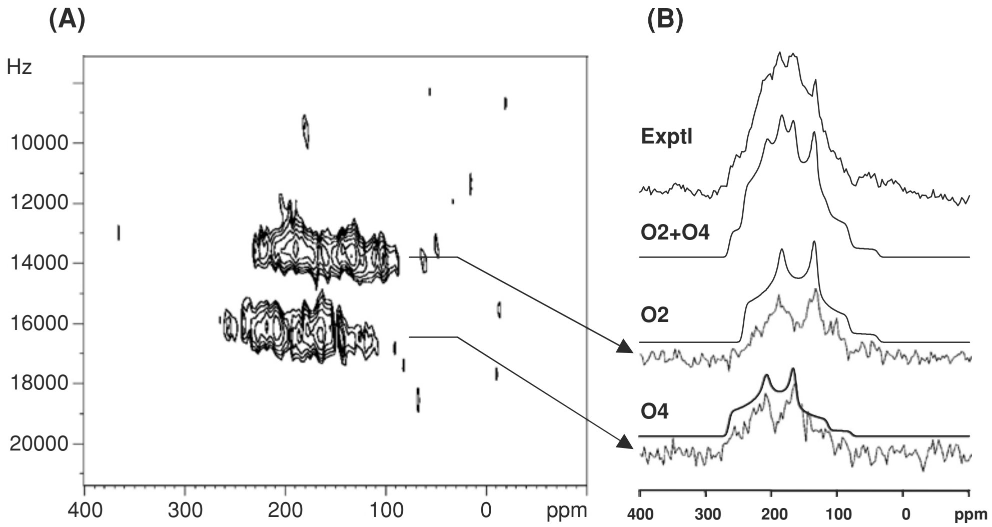

Fig. 2. (A) Experimental 2D ^{17}O 3QMAS spectrum and (B) experimental and calculated 1D ^{17}O MAS spectra for [2,4$-^{17}O_2$]uracil (≈40% ^{17}O) at 11.75 T.

Table 1 lists the organic compounds, together with the corresponding solid-state NMR parameters, so far studied by using a ^{17}O 3QMAS approach. This small collection of organic compounds includes such functional groups as carboxylate, water, amide-type, and urea-type oxygen atoms. The range of C_Q for these functional groups is between 5.9 and 8.2 MHz, typical of most oxygen-containing functional groups in organic compounds. At 11.75 T, a C_Q of this order of magnitude would give rise to a residual second-order quadrupole line width of 8–15 kHz (corresponding to 120–220 ppm for ^{17}O). For example, the line width observed in the ^{17}O MAS spectrum of uracil is 13 kHz. This kind of residual quadrupole broadening would obscure any chemical shift difference

Table 1: A summary of organic compounds studied by ^{17}O MQMAS NMR

Compound	Site	δ_{iso} (ppm)	C_Q (MHz)	η_Q
D-[$^{17}O_2$]Alanine [29]	O_1	275	7.60	0.60
	O_2	262	6.40	0.65
Potassium hydrogen [$^{17}O_4$]dibenzoate [29]	O_1	285	8.30	0.15
	O_2	215	5.90	0.90
DL-[$^{17}O_4$]Glutamic acid hydrochloride [29]	O_1	170	7.20	0.20
	O_2	250	6.80	0.58
	O_3	250	6.80	0.58
	O_4	320	8.20	0.00
[2,4$-^{17}O_2$]Uracil [29]	O_2	240	7.62	0.50
	O_4	275	7.85	0.55
L-Asparagine·$H_2^{17}O$ [30]	H_2O	7.0	7.0	1.0
Monosodium L-[$^{17}O_2$]glutamate [31]	O_1	254	7.4	0.47
	O_2	260	7.2	0.50
	O_3	274	7.6	0.45
	O_4	283	7.7	0.40
	O_5	297	7.0	0.45

between different oxygen sites, leading to a low apparent resolution in ^{17}O MAS spectra. The success of the MQMAS approach relies on the fact that this residual quadrupole broadening can be completely removed in the isotropic dimension. Still use uracil as an example. The 13-kHz line width observed in the ^{17}O MAS spectrum is reduced to about 0.5 kHz along the F_1 axis in the ^{17}O 3QMAS spectrum. This example clearly demonstrates the remarkable benefit of using ^{17}O 3QMAS to improve spectral resolution. The factor that will ultimately determine the resolution limit in ^{17}O MQMAS spectra for organic compounds is not fully understood. However, it appears that the effectiveness of ^{1}H –^{17}O dipolar decoupling plays an important role. We have also reported an unusual ^{1}H–^{17}O decoupling-induced–recoupling phenomenon that may also be important in determining the residual line width in ^{17}O MQMAS spectra [37]. More research is needed in this area. Nevertheless, the advantage of ^{17}O MQMAS over traditional ^{17}O MAS is that the high intrinsic spectral resolution associated with SSNMR can be recovered.

Sensitivity of ^{17}O MQMAS Experiments

In MQMAS experiments, sensitivity is a critical issue. Since the efficiency in both MQ excitation and MQ-to-1Q conversion is proportional to the B_1 field strength, one brute-force approach to increase sensitivity in MQMAS experiments is to improve probe hardware that can sustain a very strong B_1 field. For most commercial MAS probes designed for narrow-bore magnets, the B_1 field is below 100 kHz at the ^{17}O Larmor frequency. Another practically useful method to improve sensitivity is to use t_1 rotor synchronization (i.e. $\Delta t_1 = T_R$) [38]. Figure 3 shows a comparison between ^{17}O MQMAS spectra obtained without and with rotor synchronization for the t_1 increments. In the 2D spectrum obtained without t_1 rotor synchronization, strong spinning sidebands are present along the F_1 dimension. The advantage of this approach is that the F_1 spectral width is not limited by the sample spinning frequency. However, the presence of F_1 spinning sidebands in 2D spectra often results in low peak intensities. In contrast, the 2D spectrum obtained with t_1 rotor synchronization has a spectral width along the F_1 dimension equal to the sample spinning frequency. Consequently, all F_1 spinning sidebands are folded back onto the central band. The advantage of t_1 rotor synchronization is that this approach enhances the overall sensitivity of MQMAS experiments, especially for sites associated with large quadrupole coupling constant and chemical shielding anisotropy. As the sample spinning frequency on modern NMR spectrometers can be as high as 35–50 kHz, it is usually not difficult to achieve a sufficiently large spectral width along the F_1 dimension. For this reason, t_1 rotor synchronization is always recommended for recording ^{17}O MQMAS spectra.

To date the molecular weight of the organic compounds studied by ^{17}O MQMAS is on the order of 200 and the ^{17}O enrichment level is generally less than 40%. It is only natural to question whether the sensitivity of ^{17}O MQMAS experiments can be sufficiently high to make studies of biological macromolecules possible. Although the sensitivity of NMR experiments depends on many factors, it is still meaningful to use the existing ^{17}O MQMAS NMR data to shed some light on the feasibility of the approach for larger molecular systems. For ^{17}O MQMAS experiments, the key factors for sensitivity include (1) the level of ^{17}O enrichment of the sample, (2) the strength of the principal B_0 magnetic field, and (3) the efficiencies for both MQ generation and MQ-to-1Q conversion. Suppose that the sensitivity of ^{17}O central transition NMR experiments depends on the applied magnetic field as $B_0^{7/2}$. With a maximum level of ^{17}O enrichment, 100%, the sensitivity of ^{17}O MQMAS experiments at 21 T (900 MHz for ^{1}H) can be increased at least by an order of magnitude compared with the results shown in Figures 2 and 3 (40% ^{17}O enrichment at 11.75 T). This will make ^{17}O MQMAS experiments feasible for studying molecular systems of a few kDa with the basic pulse sequence described above. Recently, new pulse sequences have been proposed for improving 3Q excitation and 3Q-to-1Q conversion efficiencies for spin-5/2 nuclei [39–43]. In addition to the new pulse sequence development, several new methods for MQMAS data acquisition have been introduced. Rovnyak *et al.* [30] used a nonlinear sampling scheme to reduce the number of t_1 increments required to obtain high resolution. Because the number of t_1 increments is reduced, more transients can be acquired for each t_1 in a given period of time, leading to a sensitivity improvement. Gan and Kwak demonstrated two new ways for utilizing signals from all coherence transfer pathways [44]. A detailed analysis of these new data acquisition methods showed that the sensitivity of MQMAS experiments can be increased by a factor of 2–3 for spin-5/2 nuclei [45]. Finally, the overall sensitivity of the MQMAS experiment can be further increased by an order of magnitude by utilizing a train of quadrupolar Carr–Purcell–Meiboom–Gill refocusing pulses (QCPMG) [46]. Considering improvement from these new developments, we believe that it should be possible to apply ^{17}O MQMAS NMR to biomolecular systems with significant molecular weights (ca. 20–50 kDa) at 21 T.

Conclusion

The advent of MQMAS NMR has triggered a renewed interest in establishing ^{17}O as a new nuclear probe to

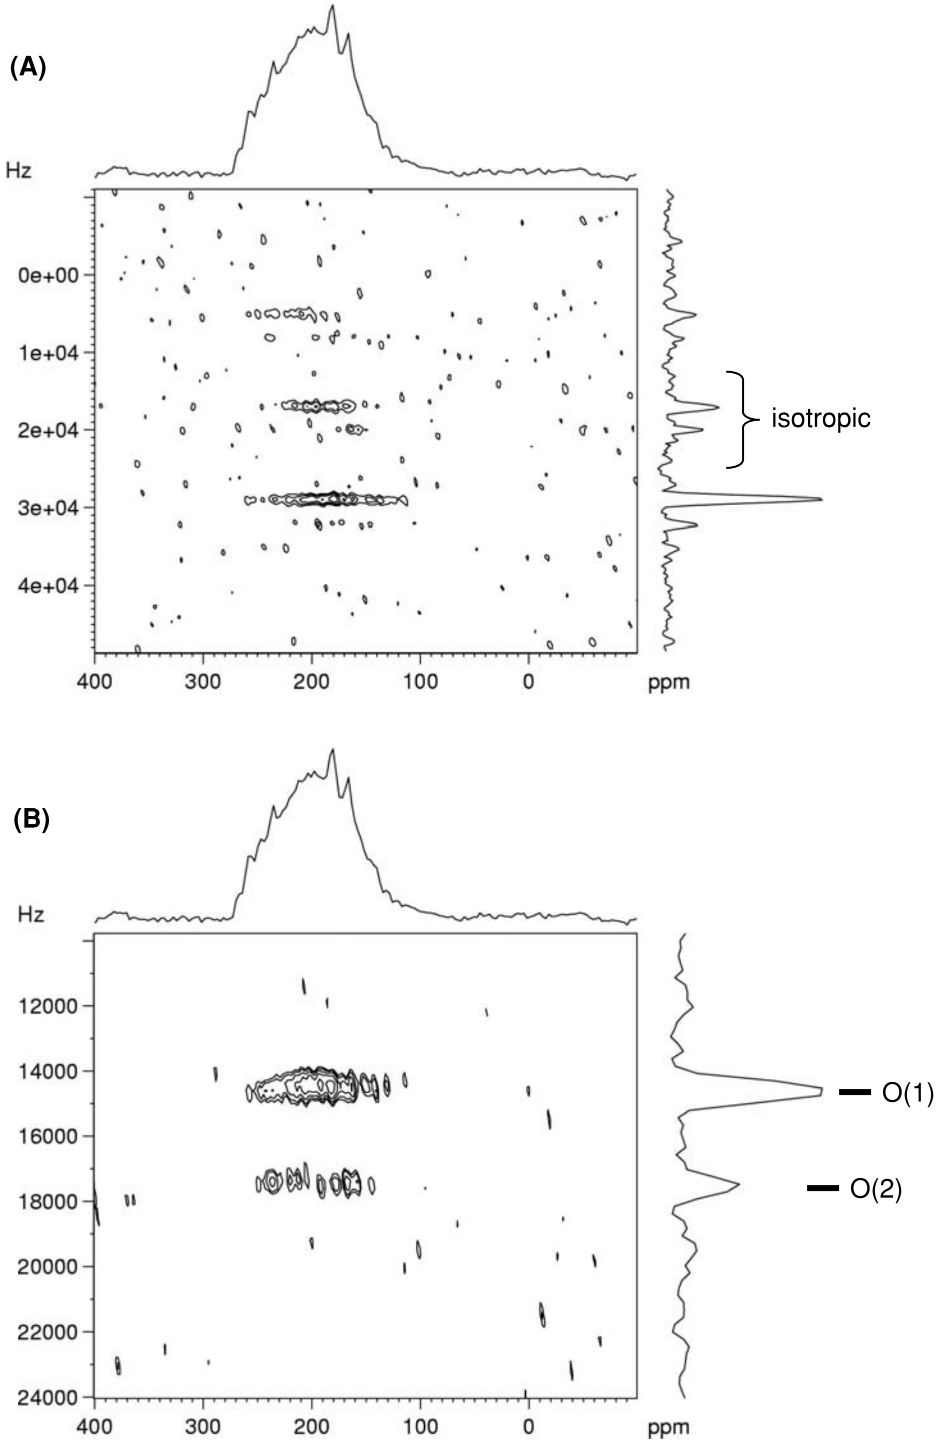

Fig. 3. Comparison between ^{17}O 3QMAS spectra for D-[$^{17}O_2$]alanine (≈40% ^{17}O) obtained (A) without and (B) with t_1 rotor synchronization at 11.75 T.

study organic and biological compounds in the solid state. The advantage of SSNMR for ^{17}O is that the ultimate spectral resolution is not restricted by molecular motion, which is often the primary obstacle in traditional solution ^{17}O NMR for biological macromolecules. Preliminary results have shown that it is possible to obtain high-quality ^{17}O MQMAS NMR spectra for organic compounds with ^{17}O quadrupole coupling constants greater than 8 MHz. Although only small organic molecules have been examined to date, the basic hydrogen bonding features in the systems studied are similar to those observed in proteins (e.g. sidechain conformation) and nucleic acids (e.g. base pairing). The demonstrated sensitivity of ^{17}O MQMAS experiments suggests that high-resolution ^{17}O MQMAS NMR can potentially become a practical technique for chemists to study organic and biological systems. It is likely that future ^{17}O MQMAS studies will have to be performed at ultra-high magnetic fields (e.g. 21 T) to gain sufficient sensitivity for studying biological macromolecules. Another challenge in ^{17}O NMR spectroscopy for biological solids lies in the synthesis of ^{17}O-enriched biological molecules.

A Family of PISEMA Experiments for Structural Studies of Biological Solids

Ayyalusamy Ramamoorthy and Kazutoshi Yamamoto
Biophysics Research Division and Department of Chemistry, University of Michigan, Ann Arbor, MI 48109-1055, USA

Abstract

Narrowest heteronuclear dipolar coupling spectral lines provided by the two-dimensional polarization inversion spin exchange at the magic angle (PISEMA) technique lead to the development and application of a series of multidimensional solid-state NMR methods for the structural studies of biological solids. Studies have shown that the measurement of structural and orientational constraints from uniformly labeled proteins using PISEMA is crucial, particularly in the structure determination of membrane-associated proteins. Excellent line-narrowing efficiency, high scaling factor, and performance at various magic-angle-spinning (MAS) speeds and radio frequency (rf) power are the main advantages of PISEMA. However, high rf power requirement and offset effects are the major limitations of this technique. In this chapter, these difficulties and methods to overcome them are discussed for both static and MAS experimental conditions. Experimental and simulated data to demonstrate the efficacy of newly developed PISEMA-type pulse sequences are also presented.

An Ideal SLF Sequence

Accurate measurement of heteronuclear dipolar couplings is very important to determine the high-resolution structure, dynamics, and orientation of molecules using solid-state NMR spectroscopy [1]. A variety of multiple pulse sequences have been used to suppress homonuclear ^{1}H spin–spin interactions in a two-dimensional (2D) separated local field (SLF) experiment, which provides narrow heteronuclear dipolar coupling lines [1]. The best sequence should: (i) completely suppress dipole–dipole interactions among I (usually high γ and/or highly abundant nuclei such as ^{1}H and ^{19}F) spins, (ii) have a large scaling factor (scaling factor $= 1.0$ represents 0% reduction in the measured I–S dipolar coupling value) in order to measure small heteronuclear dipolar couplings as well as to resolve resonances from uniformly labeled proteins, (iii) have a short duration that can provide a large spectral width, (iv) be tolerant to pulse imperfections such as offset and rf field inhomogeneity, (v) require a low rf power to avoid sample heating, (vi) avoid rotor synchronization and be independent of the spinning speed of the sample for studies under MAS, and (vii) be easy to set up in most commercially available solid-state NMR spectrometers. Among all the reported SLF sequences, polarization inversion spin exchange at the magic angle (PISEMA) (Figure 1A and B) satisfies most of these requirements [1–4]. An Flip-flop Lee-Goldburg (FFLG)- [5–8] or Phase-Modulated Lee-Goldburg (PMLG)- [9] based PISEMA sequence efficiently suppresses ^{1}H–^{1}H dipolar couplings with a scaling factor of 0.816 and a short cycle time (16.33 μs for a 50 kHz rf field strength), tolerant to most of the experimental errors, easy to set up, and can easily be modified to work efficiently under various spinning speeds without the need for rotor synchronization [1,3]. In addition, the sensitivity enhancement offered by the polarization inversion, and the reduction of relaxation rates and suppression of I and S spin chemical shifts by the spin-locks during SEMA are other intrinsic benefits of the sequence [1,2]. Therefore, the pulse sequence has been widely used for studies both under static (Figure 1A) [1,10–15] and MAS (Figure 1B) [1,4,16] experimental conditions. The SEMA sequence has also been utilized to develop several new solid-state NMR methods to study biological solids [17–23]. Studies have shown that replacing FFLG in SEMA with the Lee–Goldburg magic angle irradiation (LG)—LG-PISEMA, LG-SEMA, or LG-CP—also provides heteronuclear dipolar coupling spectra with an identical scaling factor [1,3,4,24]. In fact, LG-SEMA is routinely used to set up 2D PISEMA experiments [3] and selective transfer of ^{1}H magnetization to its dipolar-coupled heteronuclei such as ^{13}C or ^{15}N [22,23,25]. The main advantages of LG-SEMA are its short cycle time and the absence of phase transients [1,3]. However, the extent of ^{1}H homonuclear decoupling and tolerance toward rf field mismatch and rf field inhomogeneity by FFLG-SEMA is far better than that of LG-SEMA [3,24].

Offset Effects

There are some disadvantages that limit the application of PISEMA to investigate certain systems. Studies have shown that the SEMA sequence is highly sensitive to I

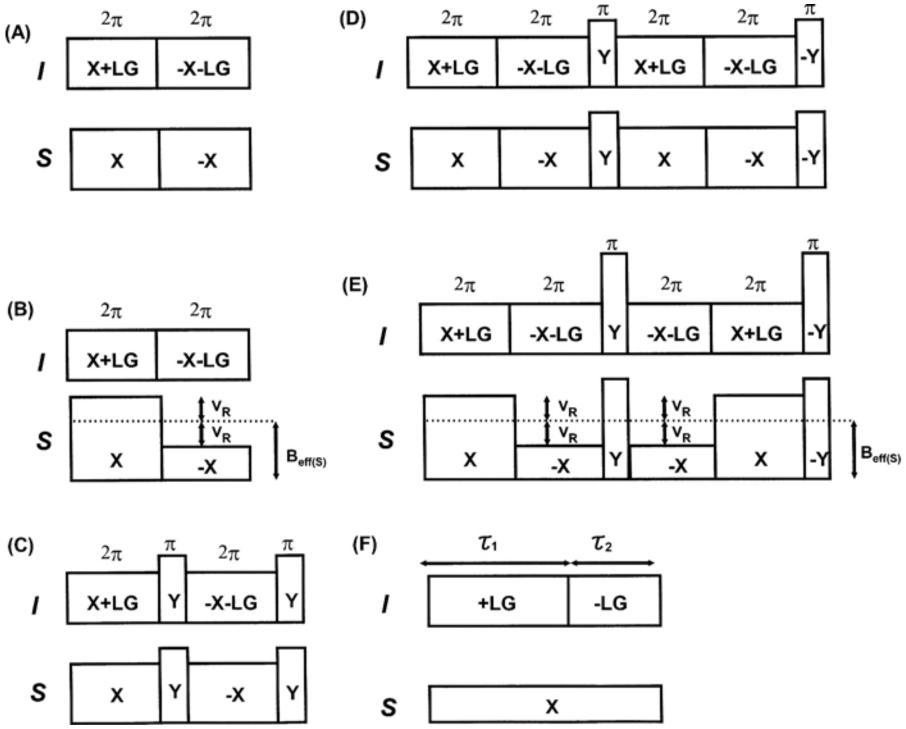

Fig. 1. Timing diagrams for a family of SEMA sequences that can be used in the t_1 period of 2D PISEMA: (A) SEMA, (B) SEMA-MAS, (C) BB-SEMA-1, (D) BB-SEMA-2, (E) BB-SEMA-MAS, and (F) TANSEMA. LG stands for the Lee–Goldburg magic angle irradiation.

spin offset [1]. Our simulations (data not shown) on a dipolar-coupled two-spin (*I* and *S*) system show that the offset dependency is identical for LG-SEMA and FFLG-SEMA sequences as there is no homonuclear ^{1}H dipolar couplings are included in the calculations. Since the effective field direction of LG or FFLG is dependent on the offset value, the line-narrowing efficiency decreases and the observed dipolar splitting increases with offset (Figure 2A, plot A). In addition, a strong zero-frequency peak appears as the off-magic angle spin-lock of *I* spins eliminates the spin exchange among *I* and *S* nuclei (Figure 3). These effects are severe when a low rf power is used and also for experiments conducted at high magnetic fields. For example, a span of ~12 ppm for amide ^{1}H chemical shift resonances makes it very difficult to satisfy the LG condition for all amide sites of a uniformly labeled protein/peptide. As a result, the intensity, scaling factor, and line width are not uniform in a 2D PISEMA spectrum of a uniformly ^{15}N-labeled protein embedded in aligned lipid bilayers. The offset effects are stronger for small ^{1}H–^{15}N dipolar couplings. Thus it is difficult to accurately measure the ^{1}H–^{15}N dipolar couplings for the structural studies of membrane proteins. Therefore, it is of considerable importance to develop new PISEMA-type pulse sequences that can overcome the above-mentioned offset effects.

Offset Compensation by BB-SEMA

Studies have shown that the use of ramped spin-lock pulses [26] during SEMA in the *S* spin channel or the newly developed SAMMY [27] sequence reduces offset effects. However, the scaling factor and the extent of line narrowing of the SAMMY sequence are smaller than that of the PISEMA sequence. We recently proposed a modified PISEMA sequence (called BB-PISEMA (Figure 1C–E) that compensates the effects of offset [28]. Introduction of simultaneous π pulses in the SEMA sequence suppresses the evolution of the magnetization under offset in the SEMA period of PISMEA. This is reflected in the results shown in Figures 2A (plots B and C) and 3. While the offset compensation is better for BB-SEMA-1 than BB-SEMA-2, line-narrowing efficiency may depend

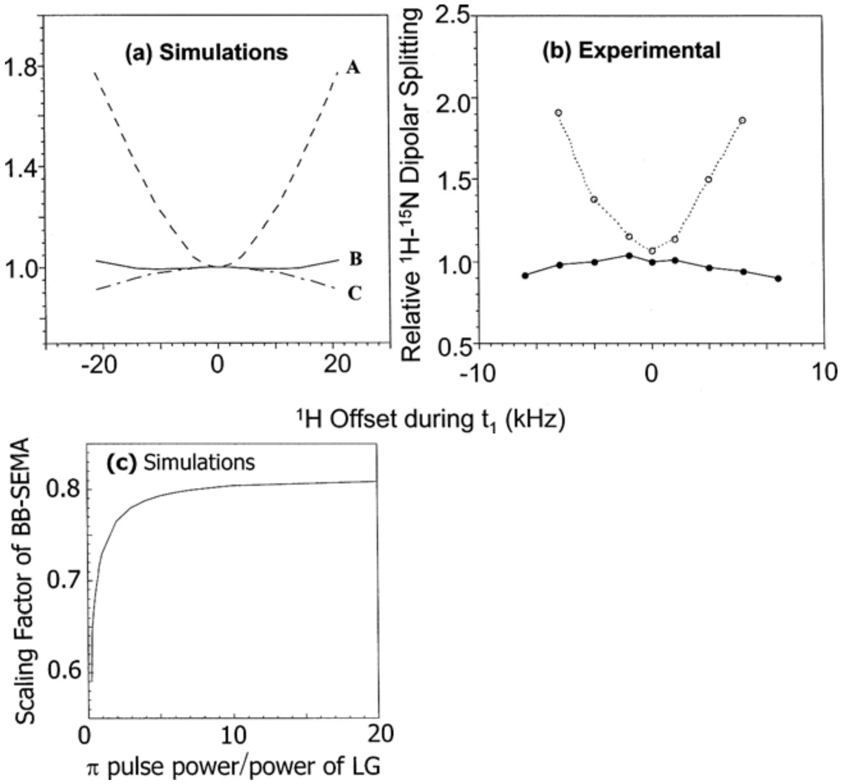

Fig. 2. Dependence of the simulated (a) and experimentally (a) measured heteronuclear dipolar couplings on the *I* spin carrier offset. Experimental data were measured from 2D PISEMA and BB-PISEMA spectra (data not shown) of *n*-acetyl-L-^{15}N-valyl-L-^{15}N-leucine single crystal under the same experimental conditions. The simulated data in (a), (b), and (c) were obtained using the PISEMA, BB-SEMA-1, and BB-SEMA-2 sequences, respectively. (c) Variation of the scaling factor with the ratio of the rf power used for the π and LG pulses in the BB-PISEMA. In all the simulations, 100 kHz rf field was used for LG and the π pulse in BB-SEMA-2. The πgulse power was varied in (c).

on the π pulse width. The number of FFLG cycles in between the π pulses can be varied depending on the required dwell time. The efficacy of SEMA (Figure 1A) and BB-SEMA (Figure 1D) sequence was examined using 2D experiments on a single crystal (Figure 2B) and simulations (Figure 2B) using SIMPSON [29]. Experimentally obtained dipolar coupling slices are given in Figure 4. Both the experimental and simulated data demonstrate that heteronuclear dipolar coupling spectra obtained using BB-PISEMA are less sensitive to *I* spin offset than those obtained with the regular PISEMA pulse sequence. This is a significant improvement and therefore the BB-PISEMA sequence can be used in the structural studies of membrane proteins at high magnetic fields where there is a range of ^{1}H chemical shifts.

Simulations suggest that the use of ideal π pulses provides a scaling factor of 0.816 and the deviation from ideality reduces the scaling factor of BB-SEMA (Figure 1C). Nevertheless, our experimental results demonstrate that the scaling factor of BB-PISEMA is 0.73 even for a π pulse width of 8.16 μs. Simulated results from an unoriented dipolar-coupled two-spin system are given in Figure 5. Recently published CSA values were used in the simulations [30–36]. FFLG-PISEMA provides better power lineshape than the LG-PISMEA sequence. However, the lineshapes from both LG- and FFLG-based PISEMA sequences are dominated by the zero-frequency peak due to *I* spin offset effects. On the other hand, BB-PISEMA significantly suppresses the offset effects (Figure 5). Offset effects of SEMA-MAS (Figure 1B) can also be compensated using a pair of π pulses as shown in Figure 1E (data not shown). While the BB-SEMA-based sequences are efficient in compensating the *I* spin offset effects even when low power π pulses were used, the

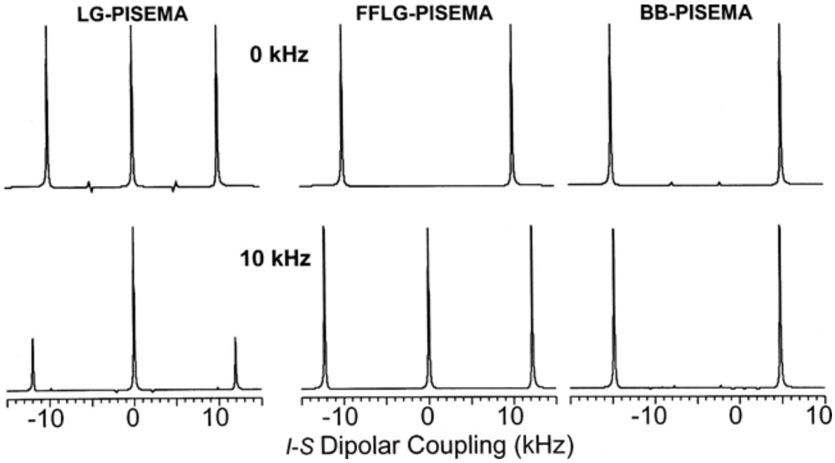

Fig. 3. Simulated I–S dipolar coupling spectra of an aligned two-spin system with a dipolar coupling constant of 10 kHz at I spin carrier offset frequencies of 0 and 10 kHz. Note the appearance of the zero-frequency peak and the increase in the dipolar splitting in LG- and FFLG-based PISEMA sequences. Offset effects are stronger when the I–S dipolar coupling is small. On the other hand, BB-PISEMA spectra are independent of the I spin carrier frequency.

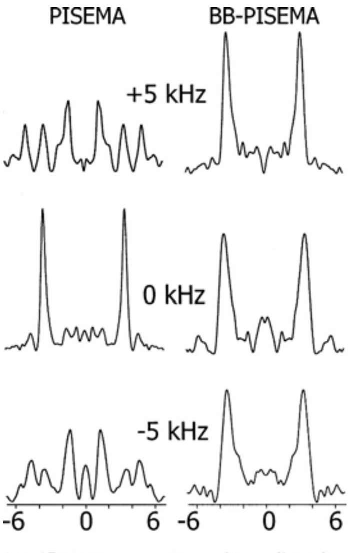

Fig. 4. Experimental ^{1}H–^{15}N dipolar coupling slices extracted from 2D PISEMA and 2D BB-PISEMA that were obtained at different ^{1}H offset values. In addition to the increase in the observed dipolar coupling values, S/N is significantly decreases with the offset value in PISEMA spectra. On the other hand, BB-PISEMA spectra are to a large extent independent of the offset values.

performances of these sequences are dependent on the Sspin offset values as shown in Figure 6 (plot B). As shown in Figure 6 (plot C), this effect can be overcome by using high power π pulses in BB-SEMA sequences. The spin dynamics and the performance of this new pulse sequence can be analyzed using average Hamiltonian and density matrix approaches. Several such studies reported the theoretical details of the offset effects under heteronuclear spin exchange process under static and MAS conditions [24,37–39].

SEMA Requires Very High RF Power

The on-resonance performance of the PISEMA sequence is impressive even when low power is used for the FFLG sequence [1,27,28]. For example, as low as a 40-kHz rf field in the ^{1}H channel can be used at 400 MHz to obtain high-resolution ^{1}H–^{15}N dipolar spectral lines for a peptide embedded in bilayers [28]. However, the requirement of rf power in the S spin channel is quite demanding as it has to match the effective field in the ^{1}H channel for static conditions: $B_{\mathrm{rf},S} = \left(B^2_{\mathrm{rf},S} + B^2_{\mathrm{off},I}\right)^{1/2}$. In addition, under MAS, the power requirement is increased by the spinning speed (Figure 1B and E); this means for experiments under fast MAS and/or at high magnetic fields, this requirement will be quite challenging to satisfy. This problem is also significant for wet biological solids such as lipid bilayers as these samples are power loss and are highly sensitive to rf heat [40–42]. For example, even in

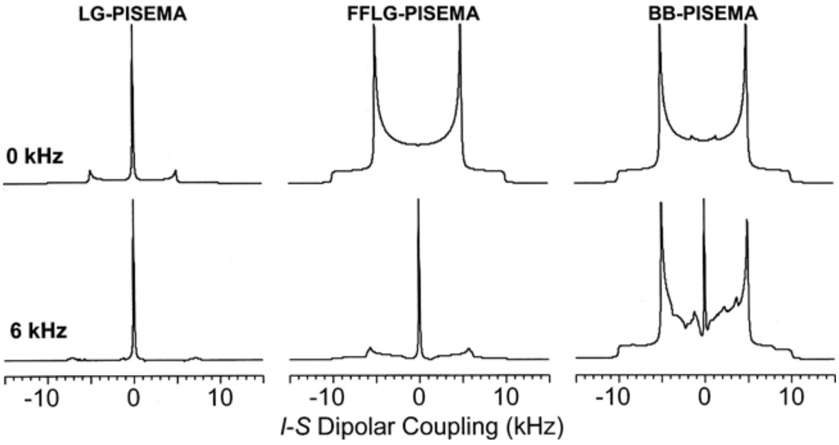

Fig. 5. Simulated I–S dipolar coupling spectra of an unoriented two-spin system with a dipolar coupling constant of 10 kHz at 0 and 6 kHz I spin carrier offset values. The strong zero-frequency peak in LG-PISEMA (both on- and off-resonances of I spin) and FFLG-PISEMA makes it difficult to measure the powder lineshape, whereas BB-PISEMA is tolerant to offset effects. The intensity of the zero-frequency peak depends on the span of the CSA values used in simulations.

the above-mentioned peptide example, ∼1 kW rf power is required in the ^{15}N rf channel [40]. Therefore, it is essential to overcome these difficulties in order to use PISEMA-type experiments on membrane proteins.

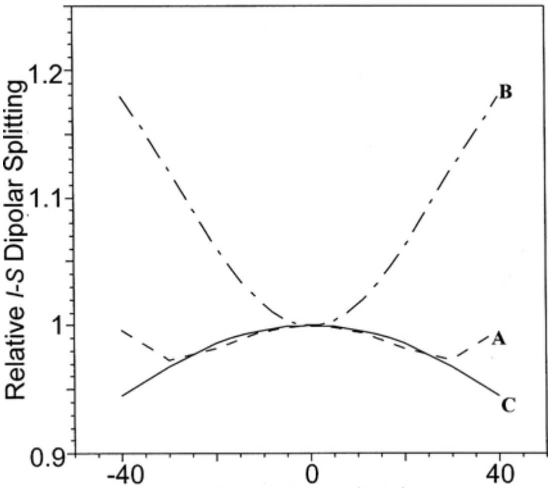

Fig. 6. Variation of simulated ^{1}H–^{15}N dipolar coupling values as a function of ^{15}N offset in PISEMA (A) and BB-PISEMA sequences (B and C). A 100 kHz rf field was used for LG in all cases, while the π pulse power was 100 kHz for (B) and 500 kHz for (C).

TANSEMA for Low RF Power Experiments

We recently demonstrated the utility of time averaged nutation (TAN) [43] concept for the reduction of rf power in SEMA experiments. The TANSEMA [44] pulse sequence shown in Figure 1F dramatically reduces the rf power required in the S spin channel. The values of t_1 and t_2 can be varied to obtain the desired effective nutation field in the ^{1}H channel. For example, PITANSEMA experiments even with a 11-fold reduction in the ^{15}N rf power, as compared to the regular PISEMA experiment, on a single crystal sample resulted in 2D spectra with line widths as good as that of PISEMA [44]. Use of supercycles and ramped spin-locks further improved the efficacy of the PITANSEMA sequence. This sequence has also shown to be effective for liquid crystalline samples [44,45]. However, our simulations show that the measured dipolar splitting is offset dependent as shown in Figure 7. Simulated I–S dipolar coupling PITANSEMA spectra of an aligned two-spin system for various I spin carrier offset values showed increase in the zero-frequency peak and the dipolar splitting like the PISEMA sequence. Research in our laboratory to improve the efficacy of PITANSEMA is in progress.

PISEMA of SI$_n$

Since the heteronuclear dipolar coupling Hamiltonians for SI$_i$ and SI$_j$ in an SI$_n$ system do not commute, the smaller couplings are suppressed by SEMA [1,45].

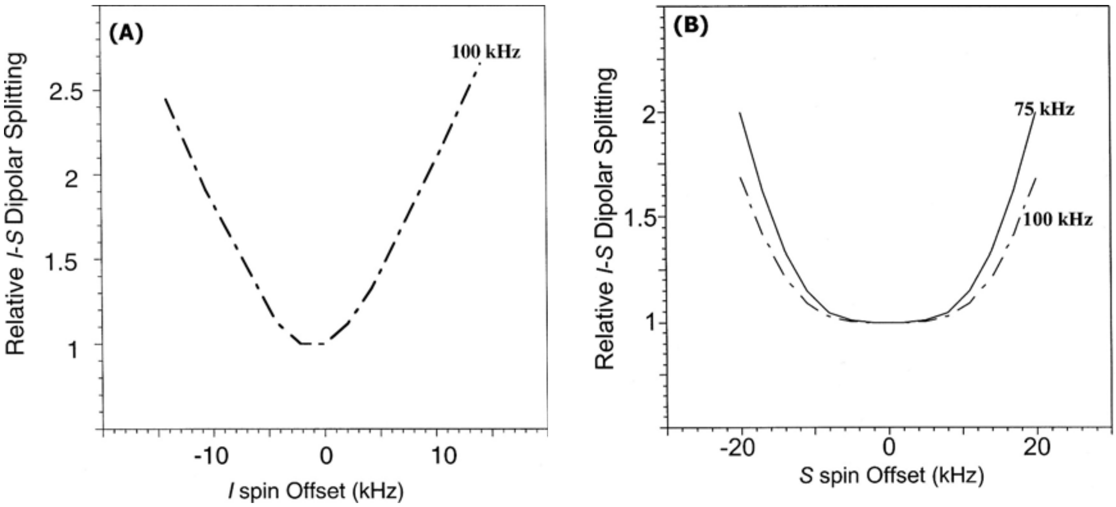

Fig. 7. Variation of simulated *I–S* dipolar splitting as a function of *I* (A) and *S*(B) spin carrier offset frequency in PITANSEMA with $\theta_1 = \pi$ and $\theta_2 = \pi/2$; where θ_1 and θ_2 are the effective nutation angles during the 1st and 2nd halves of the TANSEMA sequence, respectively (Figure 1E). Note that these angles are equal (i.e. $\theta_1 = \theta_2$) in PISEMA and therefore the time average nutation for SEMA is zero.

This is an advantage in the structural studies of proteins as one interested in measuring the dipolar coupling between the directly bonded amide ^{1}H and ^{15}N spin pairs by suppressing the coupling between remote protons and ^{15}N. However, in several other systems such as liquid crystalline materials, measurement of small dipolar couplings is important. Recent studies have showed that it is difficult to measure small dipolar couplings in the presence of large dipolar couplings [46,47].

Summary

We have highlighted the advantages and disadvantages of the commonly used PISEMA pulse sequence. Recently developed BB-PISEMA to compensate the offset effects and PITANSEMA to overcome the high rf power effects are also discussed. We believe that these new sequences further widen the applications of PISEMA. Some of the areas that benefit from these applications are the structural studies of weakly aligned molecules, bicelles, and liquid crystalline materials. It is also possible to develop a variety of PISEMA-type pulse sequences by combining these new developments with indirect ^{1}H detection, MAS, and gradients for various studies on both rigid and mobile biological solids. Needless to mention that the optimization of phase, frequency, and width of rf pulses of SEMA for better performance could also provide fruitful results.

Acknowledgments

Structural Constraints in Solids

Part I

Rotational-Echo, Double-Resonance NMR

Terry Gullion

Department of Chemistry, West Virginia University, Morgantown, WV 26506, USA

Introduction

Rotational-echo, double-resonance (REDOR) NMR is a high-resolution, solid-state NMR experiment for measuring the dipolar coupling between a heteronuclear spin pair [1,2]. The $1/r^3$ distance dependence of the dipolar coupling makes REDOR useful for the structural characterization of solids, and REDOR has become a valuable tool for characterizing a wide range of materials, including peptides and proteins, polymers, zeolites, guest–host systems, glasses, and more. Since the REDOR experiment is based primarily on trains of π pulses, it has mostly been used to measure dipolar couplings between pairs of spin $-1/2$ nuclei. Under certain conditions, however, the REDOR experiment can also make effective use of quadrupolar nuclei as structural probes.

In REDOR experiments, the NMR signal of the observed nucleus is attenuated when dipolar dephasing radio frequency (rf) pulses are applied to the non-observed nucleus. The dependence of this signal reduction on the dipolar evolution time provides a direct way to determine the dipolar coupling and obtain internuclear distances. Analysis of REDOR data involves the simple measurement of signal intensities and comparing the normalized dipolar dephased signal to a universal dipolar dephasing curve. The universal dipolar dephasing curve depends only on the dipolar coupling, and it is independent of all other NMR parameters such as chemical shift anisotropy and resonance offset. The ease of experimental implementation and straightforward data analysis are properties that make the REDOR experiment particularly attractive for structural characterization of complex molecular systems.

Dipolar Recoupling

With magic angle spinning (MAS), the time-dependent dipolar Hamiltonian for a heteronuclear pair of spin $-1/2$ nuclei is [3–5]

$$H = d(t) S_z I_z, \tag{1}$$

where

$$d(t) = d\left[\sin^2\beta \cos 2(\omega_r t + \alpha) - \sqrt{2}\sin 2\beta \cos(\omega_r t + \alpha)\right]. \tag{2}$$

The dipolar coupling, in SI units, is

$$d = \frac{\mu_0 \gamma_S \gamma_I \hbar}{4\pi r^3}, \tag{3}$$

where μ_0 is the permeability of free space, γ_S and γ_I are the magnetogyric ratios of the coupled spins, $\hbar$ is Planck's constant divided by 2π, and r is the internuclear separation. The orientation of a vector directed between the S and I spins in the rotor frame is defined by the polar angle β and the azimuthal angle α. The sample spinning rate, ω_r, is related to the period of the sample rotation, T_r, through $\omega_\mathrm{r} = 2\pi/Tr$. Inspection of Equation (2) shows that the average heteronuclear dipolar interaction is zero, and the consequence of this averaging is that the dipolar interaction has little effect on observed spectra under typical high-resolution MAS conditions. By toggling the spin states of the S and I spins synchronously with the sample rotation, it is possible to produce an average dipolar Hamiltonian that is not equal to zero and, in effect, recouple the dipolar interaction. Synchronous toggling of spin states with the sample rotation is the principle behind the REDOR experiment.

Two experiments are performed for REDOR measurements. An S-spin control signal is generated by omitting I-spin rf pulses. An S-spin dipolar dephased signal is produced by applying I-spin rf pulses. Comparison of the control and dipolar dephased signals provides a way to obtain the dipolar coupling. The concept of the control experiment is illustrated in Figure 1 (left), where neither the S-channel nor the I-channel contains any rf pulses, and the S and I spin orientations (magnetic quantum numbers) remain unchanged during the entire rotor cycle. An I spin will generate a local magnetic field, B_L, at the site of a neighboring S spin, and the S-spin transverse magnetization will precess at a rate $\omega_S = -\gamma_S B_\mathrm{L}$ in the rotating frame defined by the Zeeman interaction. In the absence of rf pulses, the physical rotation of the sample about the sample rotor axis averages the local magnetic field and dipolar Hamiltonian to zero according to Equations (1) and (2). The local field, B_L, is negative as often as it is positive. Hence, the dipolar interaction causes no net precession of the transverse component of the S-spin magnetization for the control experiment.

The S-spin dipolar dephasing experiment shown in Figure 1 (right) illustrates the principle of dipolar

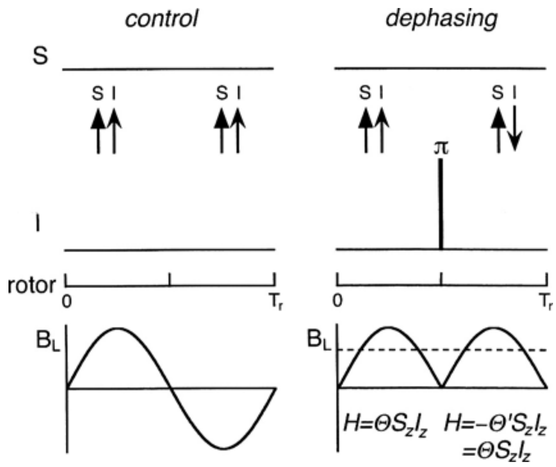

Fig. 1. Illustration of the control and dipolar dephasing experiment. Representative spin states are indicated (by arrows) for each half of the rotor cycle. For the control experiment, no change in spin states occurs. The local field, B_L, is that generated by the I spin and appearing at the S spin. Toggling frame Hamiltonians are shown for the first and second half of the rotor cycle for the dipolar dephasing experiment.

recoupling. A π pulse is applied to the I-channel at the midpoint of the rotor cycle. From time 0 to $T_r/2$, the toggling frame Hamiltonian is [6]

$$H = \Theta S_z I_z, \tag{4}$$

where

$$\Theta = \left[\int_0^{T_r/2} d(t)\mathrm{d}t\right] \Big/ \left[\int_0^{T_r/2} \mathrm{d}t\right] \tag{5}$$

which becomes

$$\Theta = \frac{2\sqrt{2}}{\pi} d \sin 2\beta \sin\alpha. \tag{6}$$

The toggling frame Hamiltonian during the time following the I-channel π pulse is

$$H = -\Theta' S_z I_z, \tag{7}$$

where

$$\Theta' = \left[\int_{T_r/2}^{T_r} d(t)\mathrm{d}t\right] \Big/ [T_r/2]. \tag{8}$$

Since

$$\int_0^{T_r} d(t)\mathrm{d}t = 0, \tag{9}$$

then $\Theta' = -\Theta$ and the toggling frame Hamiltonian for the second half of the rotor cycle is also $H = \Theta S_z I_z$. Hence, the average dipolar Hamiltonian for the dipolar dephasing experiment is not equal to zero and is

$$\bar{H} = \Theta S_z I_z. \tag{10}$$

The consequence of toggling the I spin from the perspective of the S spin is also illustrated by the local field, B_L. During the second half of the rotor cycle, the sign of B_L is opposite to that found in the control experiment for the same time period because of the sudden change in the spin state of the I spin caused by the π pulse. Consequently, the average local field (dashed line) experienced by the S spin is no longer zero, as it was in the control experiment, and the S-spin transverse magnetization undergoes a net nonzero dephasing leading to signal attenuation.

Each orientation of the S–I spin pairs in the powder sample contributes a dipolar dephased signal, s_d, to the total powder signal. This contribution is [1,2,7]

$$s_d = \cos\bar{\omega}_d\tau, \tag{11}$$

where

$$\bar{\omega}_d = 2\sqrt{2}D\sin 2\beta\sin\alpha, \tag{12}$$

and $D = d/2\pi$ has units of Hz and τ is the dipolar evolution time in seconds. A powder sum over the angles α and β provides the normalized dipolar dephased signal intensity, S_d, which is

$$S_d = \int_\beta\int_\alpha \cos\bar{\omega}_d\tau\,\sin\beta\,\mathrm{d}\alpha\,\mathrm{d}\beta \Big/ \int_\beta\int_\alpha \sin\beta\,\mathrm{d}\alpha\,\mathrm{d}\beta \tag{13}$$

Practical Details

Figure 2 shows three practical REDOR pulse sequences designed to increase the dipolar evolution period over multiple rotor cycles [8]. In order to maintain the average dipolar Hamiltonian provided by Equation (10), two π pulses per rotor cycle are required and the timing between any two adjacent π pulses is $T_r/2$. The dipolar evolution time, τ, is the rotor period multiplied by the number of rotor cycles, N_c, during the dipolar evolution period: $\tau = N_c T_r$. If the pulse spacing between adjacent π pulses differs from $T_r/2$, then Equation (13) is still applicable but Equation (12) takes on a slightly different form. For most work, the best pulse spacing is $T_r/2$.

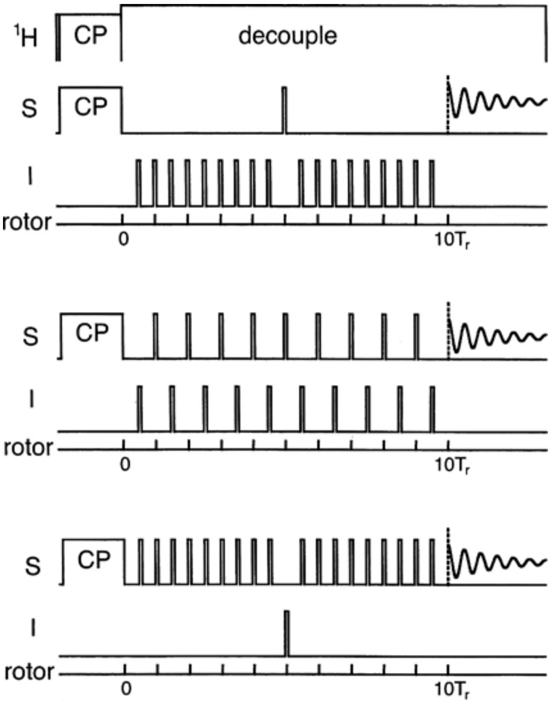

Fig. 2. Three commonly used REDOR pulse sequences. Each is shown for a dipolar evolution period of 10 rotor cycles. If protons are not available for cross-polarization (CP), then the S-channel CP pulse is replaced with a simple $\pi/2$ pulse.

Table 1: Phases of the xy-4 cycle and its supercycles

Cycle	rf phases
xy-4	xyxy
xy-8	xyxy yxyx
xy-16	xyxy yxyx $\overline{\text{xyxy}}$ $\overline{\text{yxyx}}$

The original REDOR pulse sequence is shown in Figure 2 (top). Protons, if present, are used to enhance the S-spin magnetization through cross-polarization (CP), and the protons are decoupled thereafter. A single S-spin π pulse is applied at the midpoint of the dipolar evolution period to refocus isotropic chemical shifts and produce an echo at the start of data acquisition. If no I-channel pulses are applied, then the S spins undergo no net dipolar dephasing and the detected S-spin signal serves as a control signal, S, which is used to account for T$_2$ type losses. The control signal is also referred to as the full signal. Application of the I-channel π pulse train recouples the dipolar interaction and produces dipolar dephasing of the S-spins according to Equation (13). The experimental dipolar dephased signal, S_r, (also referred to as the reduced signal) will be less intense than the control signal. The dipolar coupling can be determined by the measured ratio $\Delta S/S|_m = 1 - \frac{S_\mathrm{r}}{S}$.

The REDOR pulse sequence shown in Figure 2 (middle) provides better overall performance for S-spin refocusing and dipolar dephasing since it is more tolerant to rf pulse imperfections. Experimental problems with rf pulses arise from limited rf power, rise and fall times of pulses, phase glitches, and resonance offsets. The xy-4, xy-8, or xy-16 phase cycling schemes should be applied to the π pulses (for all three pulse sequences) to eliminate problems associated with pulse imperfections [9,10]. In most cases, the xy-8 supercycle is adequate, but the xy-16 and xy-32 supercycles may offer minor improvements. The phases of the xy-4, -8, and -16 supercycles are shown in Table 1.

The REDOR pulse sequence shown in Figure 2 (bottom) has been used whenever the I spin has a very large anisotropic interaction (either very large chemical shift anisotropies or modest quadrupolar interactions). It has been particularly useful for $I = {}^2$H, especially when the lone I-spin pulse is a composite $\pi/2$ pulse [11]. This particular pulse sequence is very sensitive to the spinning rate, which should be stabilized to within a fraction of a Hz [12,13]. The other two pulse sequences do not require such a high degree of control of the spinning rate.

Examples of REDOR spectra are shown in Figure 3, and full experimental details can be found in Ref. [14]. The observed spin is ^{13}C and the dipolar dephasing spin is ^{2}H. The sample is a 30-residue (AlaGly)$_{15}$ peptide having repeated β turns. The carbonyl carbon of Gly(14) is ^{13}C enriched and a deuteron is attached to the C$_\alpha$ carbon of Ala(17). The ^{13}C–^{2}H REDOR full spectrum (bottom) was obtained by omitting the ^{2}H rf pulse and the carbonyl ^{13}C resonance intensity provides the signal S. The reduced, or dipolar dephased, ^{13}C spectrum is shown in the middle. It is evident that the signal intensity at the carbonyl ^{13}C resonance position has been attenuated, and the measured intensity of the carbonyl ^{13}C resonance produces S_r. The difference spectrum (full minus reduced) is shown at the top and the measured signal intensity of the carbonyl ^{13}C resonance position produces ΔS. The measured ratio $\Delta S/S|_m$ is obtained by the simple measurement of signal intensities S and S_r (or ΔS).

Dipolar couplings are obtained by comparing the measured $\Delta S/S|_m$ to $\Delta S/S = 1 - S_\mathrm{d}$ from average Hamiltonian theory. Equations (12) and (13) provide S_d for $S = 1/2, I = 1/2$ spin pairs, and the ideal $\Delta S/S$ is shown in Figure 4 where it is plotted against the dimensionless

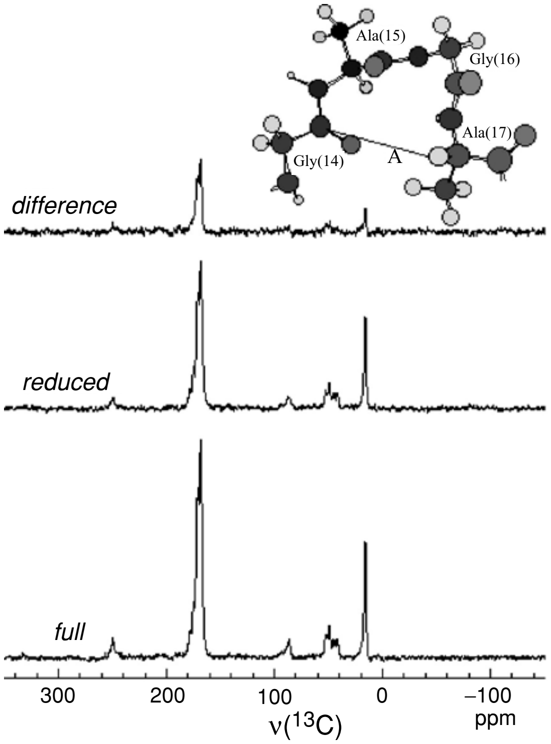

Fig. 3. Example of full, reduced, and difference ^{13}C–^{2}H REDOR spectra. Experimental details can be found in Ref. [14].

parameter $\lambda = N_c T_r D$. There are two easy ways to generate $\Delta S/S$ plots. The first is to perform a powder sum over all s_d to produce S_d, which is Equation (13). The second method is to calculate S_d using Bessel functions of the first kind, and for $S = 1/2$, $I = 1/2$ spin pairs [15]

$$S_d = \frac{\sqrt{2}\pi}{4} J_{1/4}\left(\sqrt{2}\lambda\right) J_{-1/4}\left(\sqrt{2}\lambda\right). \qquad (14)$$

The Bessel function method has the advantage of speed of calculation and, if the data set is large enough, may be used to produce dipolar frequencies via the REDOR transform.

REDOR experiments can also be performed with quadrupolar nuclei, where $I > 1/2$ [16–22]. Table 2 provides a summary of normalized dipolar dephased signals, S_d, in terms of Bessel functions and s_d in terms of cosine functions for ideal REDOR behavior for $S = 1/2$, $I > 1/2$ spin pairs. The overall width of the lineshape of a quadrupolar nucleus can be very large, depending on the size of the quadrupolar coupling constant, χ (in frequency units, $\chi = e^2 qQ/h$). Hence, it is difficult to uniformly irradiate the broad I-spin spectrum with typical rf field strengths that are available experimentally. For each value of I in Table 2, an approximate upper limit of χ is provided which was determined by assuming an I-channel rf field strength of 50 kHz. As long as χ is less than the indicated value, the experimental data should obey the REDOR dipolar dephasing equations given in Table 2 reasonably well and provide a distance within 1% of the expected value. Higher values of χ will result in REDOR dephasing of the S spins, but numerical simulations that take into account the rf field strength, resonance offsets, χ, and quadrupolar asymmetry parameter will be necessary in order to extract the dipolar coupling. The functions for $I = 1$ in Table 2 are primarily for ^2H and using the pulse sequence shown in Figure 2 (bottom). In particular, the case where the I-spin pulse is a composite $\pi/2$ pulse (instead of a π pulse) has been shown to provide good interatomic distances even for rigid deuterons, which have $\chi = 167$kHz [11]. For typical rf field intensities, a π pulse on the ^2H channel does not provide ideal dipolar dephasing except for cases where there is significant motional narrowing of the ^2H lineshape, such as for the case of methyl rotation where $\chi = 55$kHz.

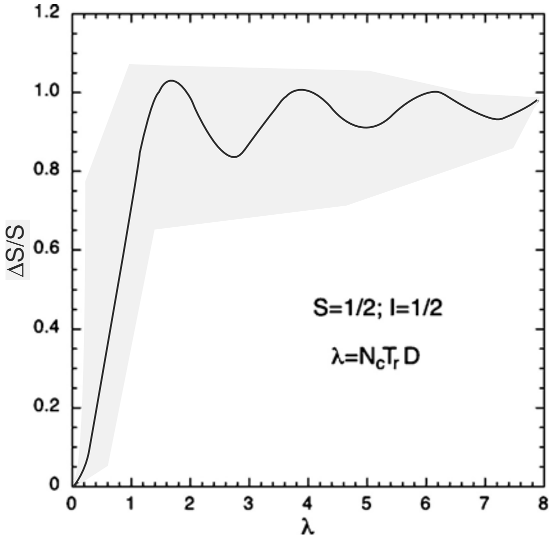

Fig. 4. Universal dipolar dephasing curve for an $S = 1/2$, $I = 1/2$ spin pair.

This chapter provided an introduction to the REDOR experiment. A more complete description of the theory can be found in Refs. [2,7]. A discussion of experimental effects, such as pulse imperfections and resonance offset, can be found in Ref. [23].

Table 2: Dipolar dephasing functions

I	$S_d(J)$	$s_d(\cos)$
1/2	$\frac{\sqrt{2}\pi}{4} J_{1/4}\left(\sqrt{2}\lambda\right) J_{-1/4}\left(\sqrt{2}\lambda\right)$	$\cos(\bar{\omega}_d\tau)$
3/2 χ < 70 kHz	$\frac{1}{2}\left[\frac{\sqrt{2}\pi}{4} J_{1/4}\left(\sqrt{2}\lambda\right) J_{-1/4}\left(\sqrt{2}\lambda\right) + \frac{\sqrt{2}\pi}{4} J_{1/4}\left(3\sqrt{2}\lambda\right) J_{-1/4}\left(3\sqrt{2}\lambda\right)\right]$	$\frac{1}{2}[\cos(\bar{\omega}_d\tau) + \cos(3\bar{\omega}_d\tau)]$
5/2 χ < 110 kHz	$\frac{1}{3}\left[\frac{\sqrt{2}\pi}{4} J_{1/4}\left(\sqrt{2}\lambda\right) J_{-1/4}\left(\sqrt{2}\lambda\right) + \frac{\sqrt{2}\pi}{4} J_{1/4}\left(3\sqrt{2}\lambda\right) J_{-1/4}\left(3\sqrt{2}\lambda\right) + \frac{\sqrt{2}\pi}{4} J_{1/4}\left(5\sqrt{2}\lambda\right) J_{-1/4}\left(5\sqrt{2}\lambda\right)\right]$	$\frac{1}{3}[\cos(\bar{\omega}_d\tau) + \cos(3\bar{\omega}_d\tau) + \cos(5\bar{\omega}_d\tau)]$

Introduction

Distance constraint is widely used in the present as a suitable means for structural characterization of a variety of molecules both in solution and in solid-state NMR. In solids, internuclear distance can be obtained by careful analysis of a specific spin pair of heteronuclear dipolar interaction, which is proportional to the reciprocal cube of the internuclear distance. In particular, rotational echo double resonance (REDOR) proposed by Gullion and Schaefer [1,2] is one of the most successful techniques to be able to determine *accurate* heteronuclear distances in solids. REDOR is a straightforward technique to recouple a weak heteronuclear dipolar interaction between an isolated spin one-half 2-spin system under MAS conditions. To this end, several intrinsic problems should be eliminated in order to obtain accurate distances leading to the three-dimensional structure of molecules. To measure the internuclear distance accurately, several experimental imperfections arising from the REDOR pulse sequence and dipolar contributions from additional nuclei as a multiple spin system should be solved. Some of them can be overcome by careful sample preparation and suitable analyses. One should be very careful in performing REDOR experiments as well as in their data analysis. In this review, we discuss how to obtain an accurate internuclear distance by REDOR. In addition, practical problems for REDOR in multiple spin systems are discussed.

Dipolar Dephasing of REDOR in I–S_n Multiple Spin System

The effect of the I–S_2 multiply dipolar coupled spin system in REDOR was first investigated by Naito *et al.* [3]. The description of the I–S_2 heteronuclear dipolar 3-spin system has been extended to the I–S_n multiple spin system later by Goetz and Schaefer [4].

In the following discussion, we define I and S as the observed and unobserved nuclei, respectively. Here we discuss a case where n number of S spins undergo heteronuclear dipolar coupling to an I spin in an I–S_n spin system. Then we derive the average Hamiltonian of the heteronuclear dipolar interaction between I and ith S spin in an I–S_n multiple spin system under the REDOR experiment at a certain orientation of the molecule as $\overline{2\omega_{\mathrm{D}_{IS_i}}\left(r_{IS}^{(i)}, \alpha^{(i)}, \beta^{(i)}, \gamma^{(i)}\right) I_z S_z^{(i)}}$. Thus the total heteronuclear dipolar Hamiltonian of an I–S_n multiple spin system under the REDOR experiment can be expressed as the sum of each dipolar interaction, $H^{\text{total}} = \sum_{i=1}^{n} \overline{2\omega_{\mathrm{D}_{IS_i}}\left(r_{IS}^{(i)}, \alpha^{(i)}, \beta^{(i)}, \gamma^{(i)}\right) I_z S_z^{(i)}}$, where the I_z and $S_z^{(i)}$ are the z components of the spin angular momentum operators for the I and $S^{(i)}$ spins, respectively. Here $\overline{2\omega_{\mathrm{D}_{IS_i}}\left(r_{IS}^{(i)}, \alpha^{(i)}, \beta^{(i)}, \gamma^{(i)}\right)}$ is the geometric part of the dipolar Hamiltonian in angular velocity units depending on the Euler angles $\alpha^{(i)}$, $\beta^{(i)}$, and $\gamma^{(i)}$, describing the orientation of the internuclear vectors between the I and $S^{(i)}$ nuclei in the rotor frame. Explicit expressions of these terms for the specific number of S spins can be found elsewhere [3–5]. The dipolar precession frequencies can be calculated using the density operator formalism [6,7]. When the initial magnetization is proportional to I_x, thus $\rho(0) = I_x$, the coherence evolved under the influence of I–S_n heteronuclear dipolar interactions can be calculated as follows [4,6,7]

$$
\begin{aligned}

calculated as follows [4,6,7]

$$
\begin{aligned}
\langle I_+\rangle &= \mathrm{Tr}[\rho(t)I_+] = \prod_{i=1}^{n} \cos\left(\overline{\omega_{D_{IS_i}}(r_{IS}^{(i)}, \alpha^{(i)}, \beta^{(i)}, \gamma^{(i)})t}\right)\\
&= m\sum_{k=1}^{2^n}(\cos\omega_k t). \qquad (2)
\end{aligned}
$$

Where m is the constant. For example, $n = 3$, eight dipolar precession frequencies in angular velocity units ω_k for an I–S_4 spin system are obtained as

$$
\begin{aligned}
\omega_1, \omega_2 &= \pm\left(\overline{\omega_{\mathrm{D}_{IS_1}}\left(r_{IS}^{(1)}, \alpha^{(1)}, \beta^{(1)}, \gamma^{(1)}\right)} + \overline{\omega_{\mathrm{D}_{IS_2}}\left(r_{IS}^{(2)}, \alpha^{(2)}, \beta^{(2)}, \gamma^{(2)}\right)} + \overline{\omega_{\mathrm{D}_{IS_3}}\left(r_{IS}^{(3)}, \alpha^{(3)}, \beta^{(3)}, \gamma^{(3)}\right)}\right)\\
\omega_3, \omega_4 &= \pm\left(\overline{\omega_{\mathrm{D}_{IS_1}}\left(r_{IS}^{(1)}, \alpha^{(1)}, \beta^{(1)}, \gamma^{(1)}\right)} - \overline{\omega_{\mathrm{D}_{IS_2}}\left(r_{IS}^{(2)}, \alpha^{(2)}, \beta^{(2)}, \gamma^{(2)}\right)} + \overline{\omega_{\mathrm{D}_{IS_3}}\left(r_{IS}^{(3)}, \alpha^{(3)}, \beta^{(3)}, \gamma^{(3)}\right)}\right)\\
\omega_5, \omega_6 &= \pm\left(\overline{\omega_{\mathrm{D}_{IS_1}}\left(r_{IS}^{(1)}, \alpha^{(1)}, \beta^{(1)}, \gamma^{(1)}\right)} + \overline{\omega_{\mathrm{D}_{IS_2}}\left(r_{IS}^{(2)}, \alpha^{(2)}, \beta^{(2)}, \gamma^{(2)}\right)} - \overline{\omega_{\mathrm{D}_{IS_3}}\left(r_{IS}^{(3)}, \alpha^{(3)}, \beta^{(3)}, \gamma^{(3)}\right)}\right)\\
\omega_7, \omega_8 &= \pm\left(\overline{\omega_{\mathrm{D}_{IS_1}}\left(r_{IS}^{(1)}, \alpha^{(1)}, \beta^{(1)}, \gamma^{(1)}\right)} - \overline{\omega_{\mathrm{D}_{IS_2}}\left(r_{IS}^{(2)}, \alpha^{(2)}, \beta^{(2)}, \gamma^{(2)}\right)} - \overline{\omega_{\mathrm{D}_{IS_3}}\left(r_{IS}^{(3)}, \alpha^{(3)}, \beta^{(3)}, \gamma^{(3)}\right)}\right). \qquad (3)
\end{aligned}
$$

So the heteronuclear dipolar interactions in an I–S_n spin system induce multiple dipolar precession frequencies, whose number is proportional to 2^n. The normalized REDOR dipolar dephasing curve S_f/S_0 can be obtained by taking powder average over heteronuclear dipolar precession frequencies as follows

$$
\frac{S_f}{S_0} = \frac{1}{8\pi^2}\int_0^{2\pi}\int_0^{\pi}\int_0^{2\pi}\langle I_+\rangle \mathrm{d}\alpha(i)\sin\beta(i)\mathrm{d}\beta(i)\mathrm{d}\gamma(i), \qquad (4)
$$

where S_f and S_0 are signal intensities obtained from REDOR and full echo, respectively. In the I–S_n multiple spin system, orientation of internuclear vectors among coupled nuclei were fixed in the molecular frame, then the internuclear vectors rotate around the magic angle axis conserving the relative orientation among them [3,5] as shown in Figure 1. This fact gives quite an important perspective for the REDOR dephasing curve implying that the curve cannot be obtained as the sum of a powder average over individual dipolar precession frequencies rather independently. Though the above Euler angles $\alpha^{(i)}$, $\beta^{(i)}$, and $\gamma^{(i)}$ in the dipolar precession frequencies do not show straightforward relationship among individual dipolar interactions, they include geometric parameters, which describe relative orientation of internuclear vectors $r_{IS}^{(i)}$ and angles among them λ_{ij} [3,5] as illustrated in Figure 1. Thus the parameterization is practically important to elucidate geometric factors from explicit forms of equations. Nishimura *et al.* showed the parameterization describing explicit geometric parameters for Equation (3) up to the I–S_3 4-spin system [5] in contrast to those derived by Goetz and Schaefer [4]. In conclusion, the dipolar interactions between additional spins do not induce an additive effect, but induce modulation effects to the largest dipolar interaction depending on the strengths of dipolar interactions and the angles between them [3–5] as shown in Figure 2.

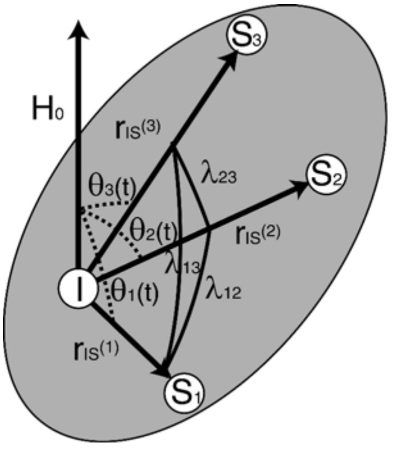

Fig. 1. Schematic representation of I–S_3 spin system which consists of the internuclear vectors (up to $n = 4$ spins) and the depending angles, where $r_{IS}^{(i)}$ are the internuclear distances between spin I and $S^{(i)}$. The λ_{ij} and θ_i are the angles between internuclear vector i and j nuclei and the angles between static field and individual internuclear vectors, respectively.

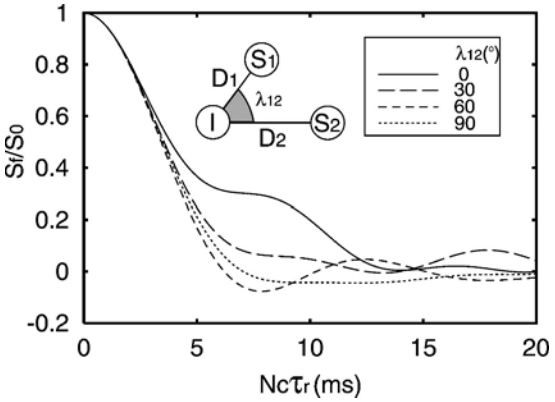

Fig. 2. The simulated REDOR dipolar dephasing curves of I–S_2 3-spin system for various angles λ_{12} between two dipolar vectors. Dipolar coupling constant D_1 and D_2 are set at 200 and 100 Hz, respectively. The angle λ_{12} vary from 0° to 90° as indicated in figure.

Obtaining Accurate Internuclear Distances by REDOR

The achieved accuracy and precisions for internuclear distances obtained by REDOR have been carefully evaluated by Naito *et al.* [8], by taking into account a variety of experimental conditions and justified with the one obtained from an X-ray diffraction study. As a result, it turned out that ^{13}C–^{15}N internuclear distance can be obtained with accuracy of ± 0.1 and a precision of ± 0.05 Å, respectively, up to the distance of 4 Å for the small peptide in the microcrystalline state [8], only when very careful experimental protocol was performed as proposed by Naito and Saito previously [9], although these kinds of precautions are very often ignored. Here, the authors discuss several important points as additional factors to obtain accurate internuclear distances, which are essential for the determination of the three-dimensional structure of a target molecule [8,10–12].

Fluctuation of RF Power, Flip Angle Errors of π Pulse and RF Inhomogeneity

First, it turns out that the accuracy in distance measurements by REDOR is quite sensitive to flip angle errors of the π pulses and RF inhomogeneity [8,13]. In practice, it is very difficult to avoid fluctuation of RF power during the long acquisition period, and it results in errors of flip angle for the π pulses. To compensate small flip angle errors for π pulses, xy-*n* (*n*: 4, 8, 16) pulse sequence proposed by Gullion *et al.* [14] is practically essential. It is advisable to set any of the π pulses in REDOR to integer multiples of these in the supercycle. Otherwise the π pulses out of the supercycle may reduce dipolar recoupling efficiency.

RF inhomogeneity among various portions of samples within the RF coil induces variation of flip angle by RF pulses, which usually reduce the recoupling efficiency of the heteronuclear dipolar interaction resulting in longer internuclear distances. As reported by Nishimura *et al.*, more than 92% RF effective field should be kept for accurate distance measurements [13] even with the use of an xy-8 or 16 compensation pulse cycle. Thus one should know the homogeneous range of RF field for individual probes. It is advisable to perform either nutation experiment to know an average RF homogeneity or signal transformation experiment as proposed by Nishimura *et al.* [13] to obtain precise RF homogeneity profile. In addition, the sample should be carefully placed in the central part of the rotor spinner within the RF coil to keep RF homogeneity more than 92% effective field.

The Finite Pulse Length and Sample Spinning Stability

Although, REDOR dephasing was analyzed based on the delta pulse assumption for π pulses, the effects of finite pulse length in the phase cycle of π pulses have to be taken into account. In practice, no significant deviations from the dephasing curve under the delta pulse may be observed in up to 10% pulse duration out of one rotor cycle as reported by Naito *et al.* [8] and Jaroniec *et al.* [15].

Furthermore, REDOR is also sensitive to the fluctuation of sample spinning rate. It has to be stabilized within a few hertz to obtain accurate internuclear distances even at moderate spinning speed. This requirement turned out to be severe when spinning speed or dipolar dephasing time is increased. The fluctuation of spinning rate results in the shifts of pulse timing, which induces reduction of recoupling efficiency.

Dipolar Interactions with Neighboring Molecules

Even though REDOR experiments are assumed to be analyzed as an isolated 2-spin system in the doubly isotopically enriched molecules, it is practically difficult to establish such an ideal spin system. This is because a set of *I* and *S* nuclei are isotopically enriched in the same molecule to which *S* nuclei of neighboring molecules are

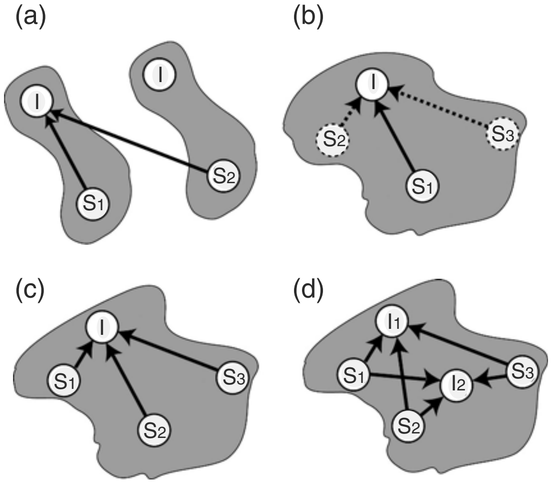

Fig. 3. The four different cases of multi-heteronuclear dipolar coupling are pictorially presented. (a) A set of isotopically enriched I and $S^{(1)}$ nuclei suffer the contribution of the intermolecular dipolar interactions from enriched $S^{(i)}$ nuclei in the neighboring molecules. (b) A set of isotopically enriched I and $S^{(1)}$ nuclei are surrounded by natural abundant $S^{(i)}$ nuclei, which provide heteronuclear dipolar coupling to enriched nuclei I. (c) I–S_n multiple spin system which consists of many enriched $S^{(i)}$ nuclei, which provide heteronuclear dipolar coupling to one I nuclei. (d) I_m–S_n multiple spin system in which both I and S nuclei are uniformly enriched.

coupled since they are located very closely as shown in Figure 3a.

Naito *et al.* [3,5,10] proposed a way to remove the contribution of intermolecular dipolar interactions by systematic dilution of isotopically labeled samples with samples of natural abundance at more than two different concentrations. For this, 60 and 30% dilution of enriched sample is advisable to keep a reasonably high sensitivity of the REDOR dephasing. The normalized REDOR dephasing values are available from extrapolating the REDOR dephasing values from different concentrations for individual dephasing times to infinitely diluted condition, because this dilution effect turned out to be linear for the concentration of enriched sample. Thus the intercept of this extrapolating line to infinitely diluted condition gives infinitely diluted dephasing values in the absence of intermolecular dipolar interaction [3,5,10]. Though extreme dilution of enriched sample has often been used to attenuate intermolecular dipolar contribution. This approach greatly reduces the sensitivity of REDOR dephasing and essentially the intermolecular dipolar contribution cannot be removed completely.

Contribution of Dipolar Coupling from Natural Abundant Nuclei

As is illustrated in Figure 3b, I and S nuclei are isotopically enriched and are surrounded by natural abundant S nuclei. Therefore, it is expected that contributions of the heteronuclear dipolar coupling from natural abundant S nuclei to enriched I nuclei should be taken into account. It is emphasized that the dipolar interactions under consideration cannot be simply treated as sum of I–$S^{(1)}$ and I–$S^{(2)}$ 2-spin system, because the enriched I nucleus is coupled to both enriched $S^{(1)}$and natural abundant $S^{(2)}$ nuclei: instead, they should be treated as $S^{(1)}$–I–$S^{(2)}$ 3-spin system as reported by Naito *et al.* [3,8,10]. As explained above, the dipolar coupling of I–S_2 3-spin system under REDOR condition can be observed as modulation effect to a larger dipolar interaction depending on its relative strengths of each dipolar interaction and the angle between two internuclear vectors. Thus, the contribution of this effect can be detected when the following conditions are satisfied. First, the natural abundant unobserved nuclei $S^{(2)}$ are located closer than the enriched unobserved nuclei $S^{(1)}$. Second, the ratio of natural abundant of S nuclei must be relatively high compared to those of observed nuclei I. Furthermore enriched nuclei I must be surrounded by a remarkable number of natural abundant nuclei S. These conditions can be found for the spin pair $I = {}^{15}\mathrm{N}$, $S = {}^{13}\mathrm{C}$ for doubly labeled peptides or proteins. However, in the case of $I = {}^{13}\mathrm{C}$, $S = {}^{15}\mathrm{N}$, the contribution from natural abundant nuclei of S is totally negligible [3]. It is important to mention that the mostly used correction of the contributed dipolar interaction from natural abundant nuclei using I–S 2-spin system has not been theoretically justified and gives rise to overestimate of the dipolar contributions. It is cautioned that the readers should be aware of a possibility of overestimate of such dipolar interactions from natural abundant nuclei by simple treatment as an I–S 2-spin system for early applications of REDOR data.

Simple Alternative to REDOR

Because the above-mentioned problems described in sections “Fluctuation of RF Power, Flip Angle Errors of π Pulse and RF Inhomogeneity” and “The Finite Pulse Length and Sample Spinning Stability” arose from methodological nature of REDOR, they could be also overcome by simple alternative variant of REDOR experiment. Simultaneous frequency amplitude modulation (SFAM) developed by Fu *et al.* [16] uses RF fields, whose amplitude and carrier frequency are sinusoidally modulated. Thus no problem arises from finite pulse length. Furthermore, SFAM keeps more than 95% recoupling efficiency at the range of more than 85% RF effective field, whose range is twice that of REDOR [13]. Thus SFAM is insensitive to the RF inhomogeneity, flip angle errors, carrier offset, and fluctuation of sample spinning rate as reported by Nishimura *et al.* [13].

C-REDOR developed by Chan [17,18] recouples heteronuclear dipolar interaction with simultaneous decoupling of homonuclear dipolar interactions among irradiated nuclei by applying phase modulated continuous RF irradiation. This property was not implemented in SFAM, and is appreciably important for precise distance measurement. Unfortunately, the scaling factor of C-REDOR is significantly small as similar to other symmetry based heteronuclear dipolar recoupling techniques such as CN [19,20] and NR [21,22] pulse sequences proposed by Griffin's and Levitt's co-workers, respectively. Many of previously developed pulse sequences including REDOR with particular number of xy-*n* pulse sequence, are also analyzed as a particular case of CN or RN pulse techniques. These techniques are theoretically sophisticated to re- and decouple particular interactions up to higher order average Hamiltonian. However, their quite small scaling factors are serious disadvantage restricting the applications to the range of the distance for useful spin pairs.

SFAM can be used as a simple alternative of REDOR to obtain accurate interatomic distances without paying many efforts mentioned above for REDOR. The accuracy and precision are justified using glycine of crystalline state with the one obtained from X-ray diffraction study [13,16]. However, it should be mentioned that the properties of the heteronuclear spin pair selectivity have not been implemented in SFAM. So the problem arising from multi-dipolar couplings are the same as conventional REDOR. In addition, the ^{1}H decoupling field must be three times as large as that of RF field for irradiated nuclei to avoid cross talk between ^{1}H and irradiated nuclei [23] in SFAM and C-REDOR. The continuous RF irradiation at strong field may induce sample heating for hydrated biological sample.

Dipolar Dephasing of REDOR in Multiple Spin System

REDOR technique itself cannot select a certain pair of heteronuclear dipolar interaction. In order to obtain accurate internulcear distance, efficient selection of spin system is essential. In the multi-site isotopically enriched sample, multi-heteronuclear dipolar interactions are observed. In Figure 3c more than two sites are isotopically enriched for *S* nuclei, which is the case of $I–S_n$ multiple spin system. And in Figure 3d both *I* and *S* nuclei are uniformly enriched, which is the case of $I_m–S_n$ multiple spin system. Though conventional REDOR cannot be applied to $I_m–S_n$ multiple spin system, in some cases, it is possible to apply REDOR to $I–S_n$ multiple spin system as explained as follows.

REDOR for $I–S_n$ Multiple Spin System

Generally, even if REDOR is applied to $I–S_n$ multiple spin system, multiple internuclear distances cannot be obtained simultaneously. It is also expected that the internuclear distance of certain pair of nuclei could be modulated as mentioned above. Two different approaches are proposed to analyze the $I–S_n$ multiple spin system.

Bertmer and Eckert reported the model free analysis of the $I–S_n$ spin system to obtain multiple distances from the multiple coupled dipolar interaction by analyzing initial REDOR dipolar dephasing using van Vleck's second moment [24]. This is based on the approximation that initial dipolar dephasing is less dependent on the relative orientation of dipolar interaction vectors. To keep the precision of results in this approach, many precise REDOR dephasing points are required. Thus, as long as a xy-*n* compensation pulse sequence [14] is used, the application of this approach is restricted to either the spinning speed in the range of fast spinning or the dipolar interactions in relatively weak range to give shallow REDOR dephasing curve.

Nishimura *et al.* [25] proposed the observation of natural abundant nuclei, which gives heteronuclear dipolar coupling to singly enriched *S* nuclei. This approach enables one to avoid problems of multiple dipolar interactions. Because individual $I–S_i$ 2-spin dipolar interactions are totally independent from relative orientation of dipolar vectors of other spin pairs, internuclear distances can be obtained simultaneously. Furthermore, it is also free from both homonuclear dipolar and scalar interactions to induce shorter T_2. This approach is applicable to the case where the sample gives no overlap of signals for observed nuclei.

Furthermore, multiple spin system can provide geometric parameters. In the $I–S_2$ 3-spin system, the heteronuclear dipolar interaction depends on three parameters such as two internuclear distances and the angle between two dipolar vectors [3,5]. When one of them were known, it is possible to obtain other two geometric parameters by explicit analysis of $I–S_2$ spin system as reported by Nishimura *et al.* [5]. In the $I–S_3$ 4-spin system, the heteronuclear dipolar interaction depends upon six parameters such as three internuclear distances, and three angles among internuclear distance vectors [5] as illustrated in Figure 1. Thus the number of parameters depending on the molecular geometry increases dramatically in proportion to the number of spins. Obviously, analysis on $I–S_3$ 4-spin system is not simple to extract the information of molecular geometry except for the special case, in which some of parameters are known or degenerated. The analysis of I–S_2 3-spin system is valid until the strength of third dipolar interaction is less than 12.5% of those of second dipolar interaction [5]. Afterward, similar analysis has been reported by Fyfe and Lewis [26].

Spin Selection Using Improved REDOR Variants

For multiple spin system, the selection of spin pair is essential. First attempt to obtain isolate I–S internuclear distance from a multi-site isotope enriched sample using REDOR variant experiment was explored by Bennett *et al.* Frequency selective dipolar recoupling (FDR) experiment [27,28], which can be applied to I–S_n multiple spin as illustrated in Figure 3c to recouple dipolar interaction between observed nuclei I and frequency selected one of the non-observed nuclei S. The frequency selectivity of S spin is achieved by the difference of isotropic chemical shift for non-observed nuclei S by applying a series of rotor synchronized $\pi/2$ pulses for non-observed nuclei S instead of π pulse in REDOR. However, this technique was practically unsuccessful because flip angle error of $\pi/2$ pulses is critically sensitive to the frequency selectivity.

Gullion and Pennington proposed θ-REDOR [29], which can be applied to I–S_n multiple spins as illustrated in Figure 3c. This is an approach to apply θ° center pulse for non-observed nuclei instead of π pulse to separate I–S_n multiple spin coherence into n number of isolated I–S spin pairs, which enable to extract multiple heteronuclear distances simultaneously. Then, Liivak and Zax [30,31] improved the sensitivity problem of dephasing in θ-REDOR, by the development of multi S spin REDOR (MSREDOR). To analyze dephasing curve, however, spin multiplicity has to be known in advance. This problem can be solved by using REDOR transformation proposed by Muller *et al.* [32], which is a direct transformation of time-domain data to a frequency-domain to exhibit dipolar precession frequencies. This technique is suitable to analyze relatively strong dipolar interactions. To exhibit visible dipolar precession peaks in REDOR transformation, many data sets of REDOR dephasing are required. Especially weak dipolar interaction due to the spin pair with longer distance is difficult to be separated. Though θ-REDOR is theoretically very sophisticated, no application using this technique for simultaneous determination of distances among multi-nuclei has been reported so far.

Jaroniec *et al.*, proposed frequency selective REDOR (FSR) [33], which can be applied to uniformly isotopically enriched sample as illustrated in Figure 3d. The frequency of particular I–S spin pair is selected by applying simultaneous soft pulses. The quality of distance measurement is theoretically equivalent to original REDOR. Except for the case where more than two observed nuclei have identical isotropic chemical shift, internuclear distances can be obtained one by one. However, the other restrictions and properties are the same as those of conventional REDOR. The uniformly enriched small peptide characterized using this technique is successfully reported [33].

Conclusions

Though many sophisticated variants of REDOR have been developed to improve the nature of REDOR, still original REDOR [1,2] experiment with xy-*n*[5] compensation pulse scheme is widely used and gives the most reliable data for practical use of distance measurements together with careful sample preparations to simplify the spin system. Because none of technique is almighty, one must chose suitable analysis and techniques depending on their purpose and situation of the samples. As a simple alternative of REDOR, SFAM [16] can be used, which is low boost to RF inhomogeneity, carrier offset and flip angle errors of pulses, if the sample is not hydrated. Thus it enables us to be free from many strict experimental restriction mentioned above for REDOR.

Torsion Angle Determination by Solid-State NMR

Mei Hong
Department of Chemistry, Iowa State University, Ames, IA, USA

Torsion angles in synthetic and biological solids encode important information on the backbone and side chain conformation of these molecules, and provide complementary structural restraints to distances. In the last decade, solid-state NMR spectroscopy has become a mature tool for determining molecular torsion angles [1]. The development of methods for measuring torsion angles in peptides and proteins has helped determine *de novo* high-resolution structures of small peptides [2–4] and solved the conformation distribution of large structural proteins [5] and synthetic polymers [6]. This review examines these torsion angle determination techniques, with a special emphasis on tensor correlation methods applied to biological solids. Both static and magic angle spinning (MAS) methods will be discussed, the former giving exquisite angular resolution, while the latter having the necessary site resolution to yield multiple angular restraints from each experiment.

Static Tensor Correlation Techniques

The correlation of two spin interactions under the static condition gives rich 2D lineshapes that depend sensitively on the relative orientation of the two tensors. One of the first static 2D techniques developed specifically for torsion angle determination is the double quantum spectroscopy (DOQSY) technique [7], which correlates the chemical shift anisotropy (CSA) of two adjacent carbons. Double-quantum (DQ) coherence, excited by a Hahn echo sequence, evolves under the sum chemical shift during t_1, and is reconverted to single-quantum (SQ) magnetization and detected during t_2 (Figure 1a). The 2D spectra correspond to $(\omega_1, \omega_2) = (\omega_a + \omega_b, \omega_{a,b} \pm \omega_D)$, where the ^{13}C–^{13}C dipolar coupling ω_D, if desired, can be removed from the ω_2 dimension using a modified magic-sandwich echo sequence [8]. The torsion angle(s) around the C–C vector is encoded in the sum frequency $\omega_a + \omega_b$. For two identical functional groups such as CH_2 groups in polyethylene, the trans conformation (180°) gives a large sum chemical shift in ω_1, while the gauche conformer (±60°) has a reduced chemical shift. The use of ^{13}C-decoupling during t_2 further distinguishes the trans and gauche conformations: the former gives a sharp diagonal spectrum while the latter has a compact and broad lineshape. This has allowed the determination of the conformational distribution in polymers [6,9].

For proteins, the DOQSY technique is best adapted to correlating the CSAs of two consecutive C′ carbons. The relative orientation reflects the torsion angles around the intervening three bonds, ω, ϕ, and ψ. Since ω is usually 180°, the DOQSY spectra depend only on (ϕ, ψ). Figure 2 shows a panel of simulated ^{13}C′ DOQSY spectra. To excite the C′–C′ DQ coherence, a two-quantum selective 90° pulse train interleaved with a train of π pulses can be applied to refocus the CSA [16]. This ^{13}C′ DOQSY experiment has been applied to spider dragline silk to show that native silk fiber has a predominant (70%) β-sheet structure with $(\phi, \psi) = (-135°, 150°)$, while silk film from the liquid extracted from the silk gland is mostly (60%) α-helical with $(\phi, \psi) = (\pm 60°, \pm 45°)$ [5].

A second static technique, separated-local-field DQ (SELFIDOQ), correlates C$^\alpha$–H$^\alpha$ dipolar coupling with C′ CSA to determine the ψ angle in proteins [10]. Here the C$^\alpha$–C′ DQ coherence evolves under C–H dipolar coupling rather than the sum chemical shift during t_1. The SELFIDOQ spectra are symmetric along the ω_1 dimension, and the 2D spectra distinguish major secondary structures such as $\psi = 120°$(β-sheet) and $\psi = -60°$(α-helix) well.

Static tensor correlation techniques give superb angular resolution for the torsion angles of interest, and are suitable for synthetic polymers or structural proteins with simple repeat sequences. However, they have low spectral sensitivity and no chemical site resolution. These are provided by high-resolution MAS experiments described below.

MAS Tensor Correlation Techniques

2D and 3D MAS techniques for determining both backbone and side chain torsion angles in proteins have been developed. The isotropic chemical shift dimension(s) in these experiments provides the necessary site resolution for extracting multiple torsion angles simultaneously from each experiment.

The first MAS technique for torsion angle determination is HCCH, which correlates two C–H dipolar couplings separated by a C–C bond [17]. ^{13}C DQ coherence is excited by a homonuclear recoupling sequence [18],

and evolves under the C–H coupling during a constant-time t_1 period. The DQ coherence is reconverted to observable magnetization by an identical recoupling period and detected. The H1–C1–C2–H2 torsion angle is encoded in the sum and difference C–H couplings, $\omega^{IS}_{jk}(t) = \sum_{m',m} b^{IS}_{jk} D^2_{0m'}(\Omega^{jk}_{\mathrm{PM}}) D^2_{m'm}(\Omega_{\mathrm{MR}}) \times \exp(im\omega_{\mathrm{r}}t)\, d^2_{m0}(\beta_{\mathrm{RL}})$. Here b^{IS}_{jk} is the distance-dependent dipolar coupling between I_j and S_k, β_{RL} is the magic angle between the rotor axis and the laboratory frame, and Ω_{MR} are the powder angles describing the orientation of the molecules in the rotor frame. The essential angular parameters that determine the torsion angle are $\Omega^{jk}_{\mathrm{PM}}$, which denote the orientation of the $I_j - S_k$ vector relative to a molecule-fixed frame. The frequencies that encode the torsion angle information are $\omega^{IS}_{11}(t)$ and $\omega^{IS}_{22}(t)$. Choosing the C1–C2 bond as the z-axis of the molecular frame, $\beta^{11}_{\mathrm{PM}} = \pi - \beta^{22}_{\mathrm{PM}}$ corresponds to the H–C–C bond angle while the difference of the two γ angles, $\gamma^{11}_{\mathrm{PM}} - \gamma^{22}_{\mathrm{PM}}$, is the torsion angle of interest. Cross terms $\omega^{IS}_{12}(t)$ and $\omega^{IS}_{21}(t)$ due to two-bond C–H dipolar couplings are readily included in the simulations.

The HCCH experiment can be applied to organic compounds containing C=C double bonds to determine the cis- and trans- configuration [12,17], and to proteins to measure side chain χ_1 angles (by H$^\alpha$–C$^\alpha$–C$^\beta$–H$^\beta$ correlation). The HCCH method has several features common to later torsion angle techniques. The use of DQ coherence allows the measurement of two dipolar couplings

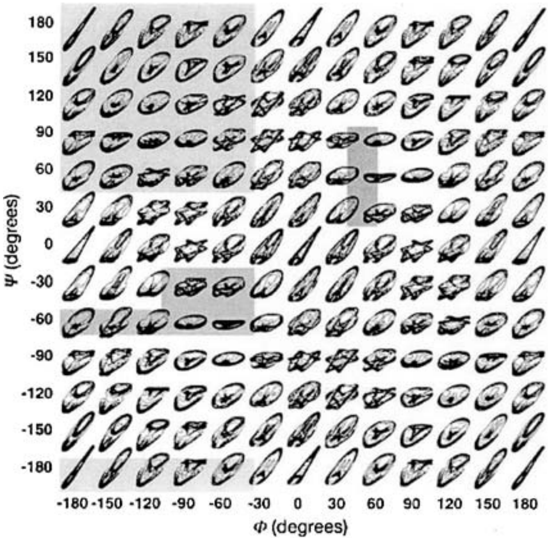

Fig. 2. Simulated DOQSY spectra of two consecutive C′ carbons in proteins as a function of (ϕ, ψ) angles. Energetically favorable areas are shaded. (Adapted from Ref. [5].)

simultaneously and suppresses natural abundance ^{13}C background. The uniaxial nature of the dipolar interaction causes a twofold degeneracy in the resulting angle. The most sensitive angular range is when the two bond vectors are antiparallel: under this condition the difference frequency nearly vanishes, giving rise to a slowly decaying time signal or a zero-frequency peak that change sensitively with the torsion angle.

ϕ Angle Techniques

The HNCH technique correlates the H^N–N and the C$^\alpha$–H$^\alpha$ dipolar couplings to determine the angle $\phi_H = H^N–N–C^\alpha–H^\alpha$ [19]. This is related to the ϕ angle (C′–N–C$^\alpha$–C′) by $\phi_H = \phi - 60^\circ$ for L-amino acids. The experiment has the same framework as HCCH, but uses ^{13}C–^{15}N heteronuclear DQ and zero-quantum (ZQ) coherence instead of ^{13}C homonuclear DQ coherence (Figure 1B). The ω_1 dimension exhibits sum and difference dipolar frequencies $\cos[\Phi_{CH}(t_1) \pm \Phi_{NH}(t_1)/2]$, where $\Phi_{XH}(t_1) = \int_0^{t_1} dt\omega_{XH}(t)$, which depend on the relative orientation of the two bonds. The method has the highest angular resolution when $\phi_H = 180^\circ$, or $\phi = -120^\circ$, thus it is particularly sensitive to the β-sheet conformation.

The angular resolution of the HNCH technique can be enhanced by doubling the N–H dephasing while holding the C–H dephasing the same as before. This N–H doubling can be achieved by modifying the N–H dipolar evolution: instead of incrementing the ^{1}H homonuclear decoupling period to define t_1, the multiple-pulse sequence is applied for a full rotor period, while a moving ^{15}N π pulse during that rotor period defines t_1 [11]. To retain the C–H dipolar phase, the C–H and N–H dipolar evolution occur sequentially instead of simultaneously. RMSDs between the experiment and simulations show that the ϕ angle resolution of the N–H doubled HNCH experiment is indeed higher than the original HNCH method. The HNCH experiment can also be modified to remove the twofold degeneracy of the ϕ angle information, by correlating the ^{15}N CSA interaction with the C$^\alpha$–H$^\alpha$ dipolar coupling [20].

The HNCH approach has been extended to 3D or reduced 3D to achieve higher site resolution [21] and to determine not only ϕ, but also ψ and χ_1 torsion angles [22]. When two frequency dimensions are used to separate the resonances, the torsion angle dimension can be simplified by sampling only two time points, the beginning and the middle of the rotor period, where the distinction between helical and sheet conformations is the largest: the β-sheet signal is retained more significantly than the α-helical signals (Figure 3a). This β-sheet selection experiment has been demonstrated on ubiquitin and indeed showed the preferential selection of the β-sheet signals [21]. One can also extract ψ and χ_1 torsion angles by correlating the N–H coupling with C–H couplings that are more than one bond removed from the ^{15}N. For ψ angles, this means N–H of residue $i + 1$ and C$^\alpha$–H$^\alpha$ of residue i. For χ_1 angles, the two tensors are the N–H and C$^\beta$–H$^\beta$ couplings of the same residue. These dipolar spectra are resolved in the 2D ^{13}C–^{15}N spectra as $^{15}N_{i+1}$–$^{13}C_i^\alpha$ and $^{15}N_i$–$^{13}C_i^\beta$ cross peaks. This 3D HNCH experiment has been demonstrated on a tripeptide, formyl-Met-Leu-Phe, and helped the determination of its high-resolution structure (0.02 Å rmsd for the peptide backbone) [2].

To make the HNCH class of experiments applicable under higher spinning speeds, which is important for uniformly ^{13}C, ^{15}N-labeled peptides, active recoupling of X–H dipolar coupling is desirable. One method developed for this purpose is the T-MREV [24] sequence, which uses semi-windowless MREV-8 as the basic element but concatenates n elements with phase shifts of $2\pi/n$ to build a C_n type pulse sequence [18]. This creates a dipolar lineshape that is independent of the MAS spinning speed, so higher spinning speeds can be used and dipolar evolution need not be confined to one rotor period. The T-MREV lineshape, in addition to its primary dependence on the torsion angle of interest, also depends on longer-range X–H dipolar couplings and the angles between multiple X–H vectors. These need to be quantified by control experiments. Among the three torsion angles (ϕ, ψ, χ_1) measurable from the 3D HNCH experiments, the angular precision is the lowest for the ψ angle because N_{i+1}–C_i^α polarization transfer is the least efficient.

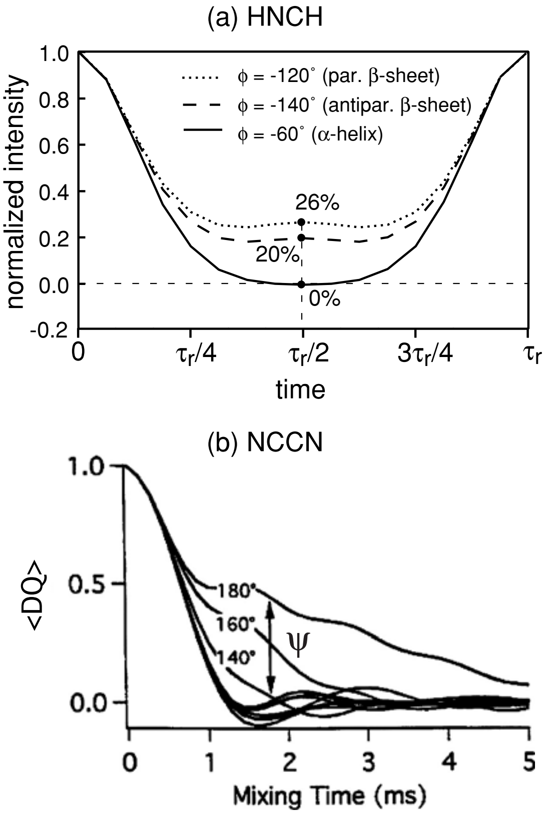

Fig. 3. (a) Characteristic HNCH time curves for ϕ angles of major secondary structures. (b) NCCN time curves for different ψ angles. (Adapted from Refs. [21,23].)

ψ Angle Techniques

Similar to the HNCH method for determining ϕ angles, tensor correlation schemes have been designed to measure the ψ angle in proteins. The simplest method is NCCN, which correlates the N_i–C_i^α dipolar coupling with the C'_i–N_{i+1} coupling [12,23]. The basic experimental design involves excitation of the C^α–C' DQ coherence and evolution of this DQ coherence under C–N dipolar coupling (Figure 1c). The exact homonuclear and heteronuclear recoupling sequences can vary [12,18,23,25], but the ψ angle-dependent signals have the same trends. The highest ψ angle resolution occurs when the N_i–C_i^α and C'_i–N_{i+1} bonds are collinear, at $\psi = 180°$. Below a $|\psi|$ of 120°, the time oscillation or spectral lineshape becomes poorly resolved (Figure 3b).

To achieve better site resolution for uniformly labeled proteins, the original NCCN experiment has been extended to incorporate two chemical shift dimensions [26]. The INADEQUATE-NCCN experiment combines 2D ^{13}C DQ–SQ correlation with NCCN evolution. In the NCOCA-NCCN experiment, the time evolution of the N_{i+1}–C_i^α correlation peak in the 2D ^{15}N–^{13}C spectra reflects the ψ_i angle. The C^α and C' coherences evolve separately under their respective ^{15}N–^{13}C dipolar interactions during a two-step polarization transfer, $N_{i+1}(t_1) \rightarrow C'_I$ (NC) $\rightarrow C_I^\alpha$ (NC) (t_2). The INADEQUATE-NCCN experiment has higher spectral sensitivity due to the one-step DQ excitation (30–35%) but somewhat lower chemical shift dispersion than the NCOCA-NCCN experiment. This was demonstrated on the model protein α-spectrin SH3 domain [26], where 13 ψ angles were measured from the INADEQUATE-NCCN experiment and 22 ψ angles were obtained from the NCOCA-NCCN experiment.

The NCCN technique is insensitive to ψ angles below ~120°, which include the α-helical conformation ($\psi = -60°$). To address this problem, an alternative tensor correlation scheme, HCCN, that exploits the H^α–C^α–C'–N topology was developed [13]. The H^α–C^α–C'–N torsion angle, ζ, is related to ψ by $\psi = \zeta + 120°$. Thus, the maximal angular resolution of $\zeta = 180°$ corresponds to $\psi = -60°$, or the α-helical conformation. This HCCN experiment recouples the C^α–H^α coupling by LG-CP and correlates it with the REDOR-recoupled C'_i–N_{i+1} interaction (Figure 1d). To increase the ψ angle resolution, the C'_i–N_{i+1} dephasing is amplified 14- to 18-fold by incrementing the C–N REDOR period 14–18 times faster than the C–H increment. Since ^{13}C′ couples to both its directly bonded ^{15}N and to the intra-residue ^{15}N, and the two-bond interaction (225 Hz) is only ~4 times weaker than the one-bond interaction, the two-bond ^{13}C–^{15}N dipolar coupling needs to be taken into account in the simulation.

In addition to dipolar based tensor correlation techniques, C^α–H^α dipolar and C' CSA correlation has been developed for determining ψ angle under MAS. One such technique, relayed anisotropy correlation (RACO) [14], yields quasi-static 2D powder patterns and is suitable at intermediate spinning speeds of ~5 kHz. The experiment selects the C' transverse magnetization over C^α, evolves it under recoupled CSA during t_1, transfers the C' magnetization to C^α, and directly detects the C^α–H^α dipolar coupling during windows of a multiple-pulse sequence (Figure 1e). The 2D RACO powder patterns are sensitive to the ψ angle, and have only minor dependence on the C' CSA tensor orientation.

An alternative technique for correlating C^α–H^α dipolar and C' CSA that is suitable under much higher spinning speeds (>10 kHz) and for uniformly labeled samples is ROCSA-LG [27]. The experiment recouples ^{13}C′ CSA in uniformly ^{13}C-labeled peptides using the ROCSA sequence [28] and probes the C^α–H^α dipolar coupling using LG-CP. In the resulting 2D ^{13}C correlation spectrum, the

C′–C$^{\alpha}$ cross peak intensity reflects the relative orientation of the two tensors.

Simultaneous (ϕ, ψ) Determination

In analogy to the static DOQSY experiment, several MAS techniques have been developed to determine ϕ and ψ angles simultaneously by correlating the orientation of two consecutive C′ CSA tensors. Common to these techniques is the creation of DQ C′ coherence to evolve under the sum chemical shift tensor. When the DQ state was prepared using the dipolar recovery with a windowless sequence (DRAWS) sequence [29], the method is called DQDRAWS [30]. Information on the relative CSA tensor orientation is contained in spinning sideband intensities [31]. The DQDRAWS sideband spectra for major secondary structure motifs are readily distinguishable. In the DQCSA experiment [15], an RFDR sequence is used to excite the DQ coherence, and the CSA recoupling is achieved by a moving π pulse in the rotor period (Figure 1f). The t_1-dependence of the sideband intensities gives the (ϕ, ψ) angle information. Figure 4 shows the simulated DQCSA t_1 signals of the center band and first-order sidebands for major secondary structures. As can be seen, the time oscillations differ significantly.

The second approach for measuring ϕ and ψ simultaneously relies on the excitation time-dependence of the C′–C′ DQ coherence. The constant-time DQ filtered dipolar dephasing (CTDQFD) experiment [32] uses three RFDR periods with durations of $L\tau_r$, $M\tau_r$, and $N\tau_r$ to select and evolve the DQ coherence. The total RFDR time $(L + M + N)\tau_r$ is constant to minimize the effects of transverse relaxation and residual ^{13}C–^{1}H dipolar coupling on the DQ dephasing curve, while the effective dipolar dephasing time is $(L + M - N)\tau_r$ [32].

The third approach for simultaneous (ϕ, ψ) determination is by detecting cross peaks between the sidebands of two consecutive C′ groups in a 2D MAS ^{1}H-driven ^{13}C spin diffusion spectrum [33,34]. Slow spinning speeds need to be used to ensure a sufficient number of sidebands. The cross peaks of interest, $V_{n,n'}^{i,j}$, are between sideband n of site i and sideband n' of site j. These inter-residue cross peaks run perpendicular to the spectral diagonal. This 2D MAS exchange experiment is simple and robust, and is suitable for chemically synthesized peptides [35], where ^{13}C′ labeling is straightforward. In applying the technique,

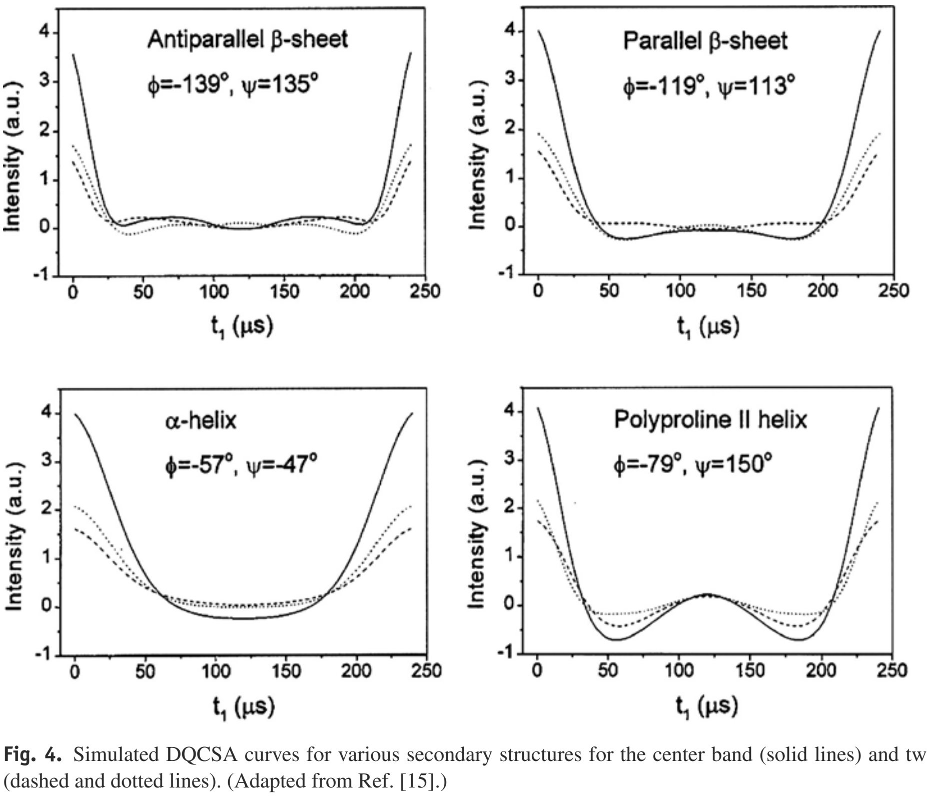

Fig. 4. Simulated DQCSA curves for various secondary structures for the center band (solid lines) and two first-order sidebands (dashed and dotted lines). (Adapted from Ref. [15].)

intermolecular spin diffusion needs to be avoided by diluting the labeled peptide in an excess of unlabeled peptide. It is also important to actively synchronize the t_2 and t_1 periods.

Distance Methods for Determining Torsion Angles

In general, the distance (d) between two atoms separated by three covalent bonds depends on the torsion angle θ around the central bond sinusoidally as:

$$d^2 = c_1^2 + c_2^2 + c_3^2 - 2c_1c_2\cos\alpha_1 - 2c_2c_3\cos\alpha_2 + 2c_1c_3\cos\alpha_1\cos\alpha_2 - 2c_1c_3\sin\alpha_1\sin\alpha_2\cos\theta, \quad (1)$$

where α_1 and α_2 are bond angles and c_1, c_2, and c_3 are bond lengths. Both homonuclear and heteronuclear distance experiments have been developed to measure such torsion angle-dependent distances. The most obvious candidate is the distance between two consecutive C′ carbons, which encodes the ϕ angle. The DRAWS recoupling sequence has been used to measure this homonuclear coupling. Application to a hexapeptide bound to hydroxyapatite crystals [36] showed the peptide to have a distribution of conformations.

Techniques for measuring heteronuclear distances between ^{1}H and ^{13}C or ^{15}N spins have also been developed to determine torsion angles. The ϕ angle can be extracted from the intra-residue H^N–C′ distance, while the χ_1 angle can be measured from the H^β–N distance [37]. The angle-dependence of these two distances is shown in Figure 5. This ^{1}H–X REDOR technique requires the detection of a third nucleus, Y, to select the REDOR modulation of the proton of interest. The ^{1}H magnetization evolves under the REDOR-recoupled dipolar local field of the X spin while ^{1}H homonuclear decoupling is achieved using multiple-pulse sequences. The selection of a specific proton is achieved by a short LG-CP to the directly bonded Y spin. Compared to the HNCH technique, the H^N–C′ method for ϕ angle determination has the advantages that it can be applied to Gly, and it is sensitive to both β-sheet and α-helical conformations.

ϕ, ψ angles can also be extracted using ^{2}H–X REDOR. The $^{13}C'_{i-1}$–$^2H_i^\alpha$ distance depends on the ϕ_i angle while the $^{15}N_{i+1}$–$^2H_i^\alpha$ distance depends on the ψ_i angle [38]. When the ^{2}H channel is unobserved, efficient inversion of ^{2}H spins is imperative for the technique to work. Vega and coworkers showed that phase-modulated XYXYX (PM5) composite 180° pulses improve the REDOR dephasing by ^{2}H spins [39]. The recoupling efficiency of this PM5-REDOR is found to approach REAPDOR but without the disadvantage of a fast-decaying S_0 that results from multiple 180° pulses on the observed channel. The method has been demonstrated on model tripeptides.

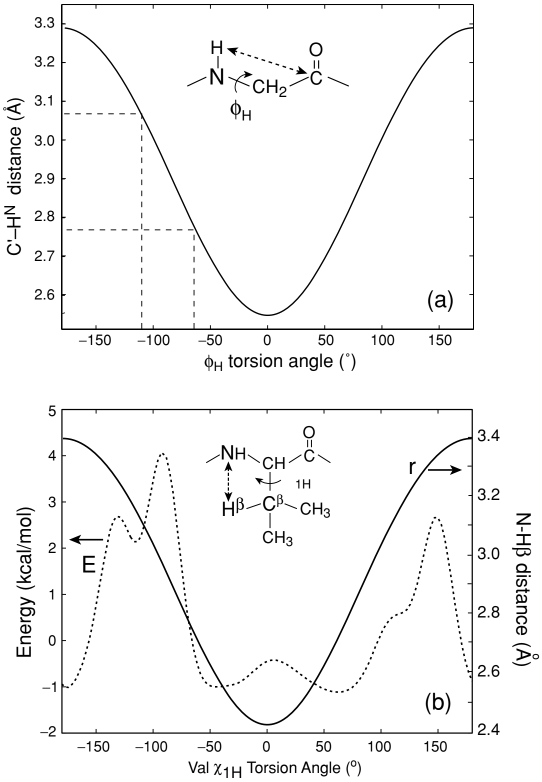

Fig. 5. Dependence of the intra-residue (A) H^N–C′ distance on the ϕ angle, and (B) H^β–N distance on the χ_1 angle. (Adapted from Ref. [37].)

Conclusion

Solid-state NMR spectroscopy has become a sophisticated and versatile tool for determining torsion angles in polymers and proteins. The principles of these techniques are perfectly applicable to other biological solids such as nucleic acids and to organic compounds [9,17,40]. These torsion angle restraints are particularly useful for defining the local conformation of molecules, and complement distance restraints, which better define the global structure of molecules.

Secondary Structure Analysis of Proteins from Angle-Dependent Interactions

Toshimichi Fujiwara and Hideo Akutsu
Institute for Protein Research, Osaka University, Suita, Osaka 565-0871, Japan

Introduction

The backbone structures of proteins are characterized by the secondary structure, such as α-helix, β-sheet, and turn structures [1]. Thus, backbone segments in the 3D structures can be assigned to these regular conformations. Information on the secondary structure is obtained at earlier stages of the experimental structural analysis by circular dichroism (CD), infrared absorption (IR), chemical shifts in nuclear magnetic resonance, and X-ray diffraction at low resolution [2]. The secondary structure analysis is the basis for the further detailed structural studies.

NMR spectroscopy provides means for the secondary structure analysis through J couplings, isotropic and anisotropic chemical shifts, and dipolar couplings [3]. In this chapter we review the NMR methods for the secondary structure analysis through the angle-dependent nuclear magnetic interactions.

Characterization of the Secondary Structure in Proteins

The secondary structure can be specified by backbone dihedral angles for consecutive residues and distances with the hydrogen bonding patterns [1]. For example, α-helix has backbone dihedral angles $\phi = -57^\circ$, $\psi = -47^\circ$, a helix diameter of 4.6 Å, and a hydrogen bond length of 3.0 Å between O in the ith residue and N in the $(i + 4)$th residue. These angles and distances give the same backbone structure. We can analyze the secondary structure through these structural parameters obtained by NMR as shown in the following sections.

NMR Methods for the Secondary Structure Analysis of Proteins

Chemical Shifts Depending on the Secondary Structure

Isotropic and anisotropic chemical shifts of ^{13}C, ^{1}H, and ^{15}N spins are influenced by the conformation through the backbone and side chain torsion angles, hydrogen bonding, electrostatic interaction, ring current, and so on [4]. Carbon-13 chemical shifts of C′, C$^{\alpha}$, and C$^{\beta}$ are shown to be primarily determined by backbone torsion angles. The torsion angles have also strong effects on the ^{15}N and ^{1}H chemical shifts. These properties have been used to identify the secondary structure in the proteins [5].

The progresses in NMR structural study of proteins and quantum mechanical analysis of chemical shifts elucidate the relationships between the chemical shifts and the structure. These relationships allow the reliable analysis of the secondary structure from the chemical shifts. The empirical and quantum mechanical database software for proteins chemical shifts are recently developed. TALOS [6] predicts the dihedral angles from the experimental chemical shifts. The other programs, TANSO [7], SHIFTS [8,9], SHIFTX [10], PROSHIFT [11], and XPRSI [12], calculate the chemical shifts from the structure given by atomic coordinates. The chemical shifts over 3–4 residues are evaluated to identify the secondary structure, because the typical secondary structure is formed by more than three amino acid residues.

Carbon chemical shift changes due to the secondary structure are about 3–5 ppm. Chemical shift is sensitive to the minor conformational distributions, which often cause the ^{13}C line width of about 1 ppm for well-ordered peptides in solid-state NMR [13]. The conformational fluctuation of proteins in solution and crystalline states generally suppresses these inhomogeneous broadening and provides sharp signals [14].

Denatured proteins generally give sharp signal at chemical shifts for random coil in solution. In this state, peptides take conformations for α and β structures in torsion angles with exchange rates larger than the resonance frequency difference. However, in solid states especially at low temperatures, random coil peptides give broad signals reflecting the distribution of the backbone structure [15]. Note that the definition of the randomness of structure depends on the experimental methods. Conformation for the CD spectrum for random coil corresponds to the structures that are not assigned to the regular secondary structures. Peptide segments that do not give definite electron densities in X-ray structure

Graham A. Webb (ed.), Modern Magnetic Resonance, 735–740.
© 2008 *Springer.*

are classified into the disordered. Although these segments would not be located at ordered sites in unit lattice, the segments may form a secondary structure. Thus, amino acid residues for the random coil in CD and the disordered in X-ray structure may not have a structural distribution that causes a random coil NMR signal.

Chemical shift anisotropy of carbons also depends on the dihedral angles as shown in recent experimental studies similarly to isotropic chemical shifts [16].

J Coupling Depending on Backbone Torsion Angles

Scalar coupling is determined by the electronic structure as well as chemical shifts. Vicinal ^3J coupling constants depend on a torsion angle as shown in Karplus curve. It was also shown that one-bond CH ^1J coupling depends on the secondary structure [17]. The $^1\mathrm{H}^{\mathrm{N}}$–$\mathrm{H}^{\alpha}$ and $^1\mathrm{H}^{\alpha}$–$^1\mathrm{H}^{\beta}$ ^3J coupling constants provide the constraints on dihedral angles ϕ and χ_1 in proteins, respectively [3]. The trans conformation can be determined uniquely from the vicinal J coupling constants. However, the gauche and cis conformations cannot be determined because ^3J coupling constants for these conformers correspond to two torsion angle in the Karplus curve. Note that the exchange between rotamers averages the J coupling constant. Since ^{1}H–^{1}H ^3J coupling constants, ca. 10 Hz, are much small than the line width of solid-state NMR signals, J coupling constants measurements for the secondary structure analysis is now exclusively used in solution NMR.

Distance Measurements for the Secondary Structure Analysis

Internuclear distances are measured from dipolar couplings by NOE in solution NMR, and REDOR [18], rotational resonance [19], and ^{1}H-driven spin diffusion [20] in solid-state NMR. Some internuclear distances are sensitive to the secondary structure, e.g. distances between C^{β} in the ith residue and C′ in the $(i + 3)$th residue is 4 Å for α-helix and 9 Å for β-structure. These distances serve as constraints in the structure determination by restrained molecular dynamics calculation. The secondary structure can be assigned in the determined ternary structure. The measurements of intramolecular distances between residues that are separated in the amino acid sequence and intermolecular distances are crucial for the structure determination of proteins. The structure determination only by the torsion angles tends to have amplified errors in those long-range distances. In comparison with experiments for signal assignments that provide chemical shifts, distance measurements need higher sensitivity especially to obtain longer distances because of the weakness in the long-range dipolar interactions.

Angle Measurements from the Anisotropic Nuclear Magnetic Interactions

The angular information is obtained from dipolar couplings and chemical shift anisotropies, because these interactions specify the directions through the principal axes of their tensors. There are several methods for obtaining the orientational information from the anisotropic interactions as follows:

Orientation Relative to the Anisotropic Nuclear Magnetic Interaction[21]

This method can be applied to powdered samples as well as oriented ones. At least two anisotropic interactions are correlated as shown in Figure 1a. The distances of spins for the angle measurements are generally less than 5 Å depending on the dipolar or J couplings employed in the experiments to correlate the anisotropic interactions. The obtained correlation spectrum provides the torsion angle constrains for the secondary structure. The details of the experiments for proteins are given in the section on torsion angle measurements.

Orientation Relative to the Tensor for Anisotropic Molecular Motion

This method provides the information on the angles of the anisotropic nuclear magnetic interactions with respect to the anisotropic rotation axes as shown in Figure 1b. This principle can be applied to ellipsoidal proteins and molecules in anisotropic environment as in the lipid membrane under unoriented states. The anisotropic axes are determined by the structure of macromolecules and the interaction of the molecule to the environment. When they undergo rapid overall rotation, the anisotropic tensor can be a rotational diffusion tensor. The angle information is obtained from the relaxation parameters [22]. The long-range angle information can be obtained by this method, because the orientations of anisotropic interactions are determined with respect to an overall diffusion tensor common to the whole molecule. When the molecules do not rotate freely as sample systems for solid-state NMR, the anisotropic axes of the molecules are primarily characterized by an anisotropic potential that restricts the molecular motion [23]. In this case, the angle information is obtained from specific reductions of powder lineshapes in frequency as well as from the magnetic relaxation. For example, rapid uniaxially rotational diffusion gives an axially symmetric powder pattern, whose maximum is determined by the orientation of the rotational axis relative to the chemical shift tensor.

Fig. 1. (a) Mutual orientation of anisotropic interactions. The shaded ellipsoids stand for anisotropic interactions which are correlated with ^{13}C–^{13}C dipolar or *J* couplings. (b) Orientation of anisotropic interactions with respect to the molecular frame that characterizes the molecular motion. The molecules rotate anisotropically in a cone. The ellipsoid indicates the anisotropy of the molecular motion that is expressed by a rotational diffusion tensor. (c) Anisotropic interactions with respect to the macroscopically orientated molecules in the laboratory frame. Anisotropy of the molecular orientation is expressed by the alignment tensor given by the ellipsoid.

Orientation Relative to the Macroscopic Orientation Axis

This category of the methods is applied to uniaxially or weakly oriented systems (Figure 1c). Spectra for these sample states provide the orientations of the anisotropic interactions relative to the macroscopic orientation axis. These orientational constraints are the source of the structural information of molecules. Torsion angles can be measured by this method [24,25]. Combining the angle constraints with respect to the orientation axes for consecutive residues, we can deduce the angle information on the secondary structure. For example, PISA wheel spectral patterns in the PISEMA spectra for NH dipolar vs. ^{15}N CSA correlation [26–28] and dipolar coupling as a function of residue number, dipolar wave [29], elucidate the angles for the secondary structure and the orientation of molecules with respect to the orientation axes. The relative orientation of anisotropic nuclear magnetic interaction with respect to the orientation axes are obtained from splittings for dipolar interactions and from frequency shifts for chemical shift anisotropies in weakly oriented systems [30]. Angle measurements over a long range such as mutual orientation of domains are also possible, because the angles with respect to the common alignment frame are measured [31].

Torsion Angle Measurements from the Mutual Orientation of Anisotropic Interactions for the Secondary Structure Analysis

In the following we will describe the torsion angle measurements from the mutual orientation of tensorial interactions and its application to peptide secondary structure analysis mainly in solid states.

Experiments for the Mutual Orientation of Anisotropic Interactions

There are two methods for the correlation of anisotropic interactions. One method for the measurement of the correlation uses two-spin coherences such as double-quantum (DQ) and zero-quantum (ZQ) coherences. This method has one period for the evolution of the two-spin coherence under two anisotropic interactions [32–36]. The DQ/ZQ evolution period is generally placed between the conversion periods between DQ/ZQ and SQ coherences in the pulse sequence as shown in Figure 2A. Anisotropic interactions were recoupled when the experiments are carried out under magic-angle spinning conditions, which improve the signal sensitivity and resolution [37].

The other method for the correlation has two evolution periods under anisotropic interactions [38–45]. The two evolution periods for the different spins are connected by a mixing period as shown in Figure 2B. The resultant 2D spectra provide the correlation that depends on the mutual orientation of the anisotropic interactions. Figure 3 shows that the correlation spectrum of CH dipolar couplings in an H–C–C–H moiety depends on the torsion angle about the C–C axis [39].

When the spins for anisotropic interactions are separated by one bond, the correlation can give the torsion angle in general. When they are separated by more than one chemical bond, the correlation can provide the information on the multiple torsion angles. When they are not separated by a chemical bond, the correlation includes the information on the bond angle and the orientation of principal axes of the chemical shift tensor. This method can be a 1D experiment [46]. Although the correlation between anisotropic interactions provides angle information, dihedral angles may not be determined uniquely because of the symmetry in the interaction. The combinations of other anisotropic interactions for the measurement of the same torsion angle or energy constraints would allow the unique determination of the angle.

Similar method has been applied to the dihedral angle measurements in solution NMR. The cross-correlation of the anisotropic interactions affects the relaxation of two-spin coherences. This cross-correlation effect has been shown to be sensitive to the mutual orientation of anisotropic interactions in solution states [47].

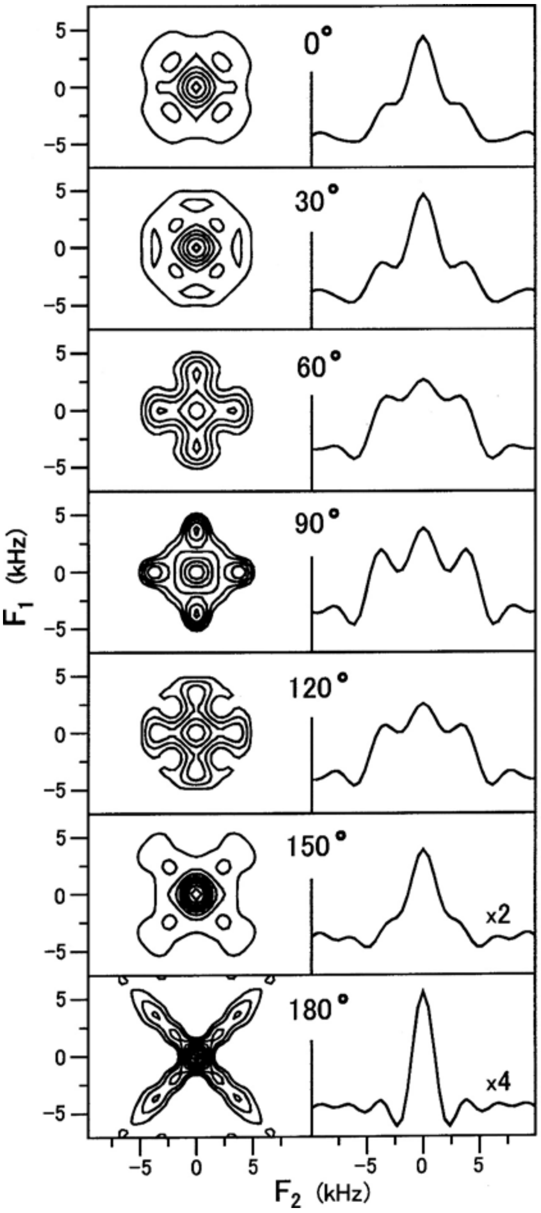

Fig. 3. Simulated 2D spectra for the correlation between CH dipolar couplings in the ^1H–^{13}C–^{13}C–^1H spin system obtained with a recoupling pulse sequence under magic-angle spinning. Cross sections along the F_2 axis at $F_1 = 0$ is also shown.

	C^α–C_1' D	
	C^α–N_1 D	

Fig. 4. Combinations of anisotropic interactions for the backbone torsion angle analysis. Anisotropic interactions specifying the orientation of atoms, N, C^α, and C′ in the backbone are shown in the first, second, and third columns, respectively. CSA and D are abbreviations for chemical shift anisotropy and dipolar coupling. The torsion angle ϕ affects the correlations between the interactions in the first and second columns, and the angle ψ affects the correlations between the interactions in the second and third columns. Note that C^α–N and C^α–C′ dipolar couplings in the second column have minor effects on the correlation for the measurements of ϕ and ψ, respectively.

Applications to the Backbone Torsion Angle Analysis of Peptides

Chemical shift anisotropies and dipolar couplings for N, C^α, and CO spins on the peptide plane can be used for the torsion angle measurements from their correlations. The carbon and nitrogen spins must be labeled with ^{13}C and ^{15}N for the high signal sensitivity and resolution.

Combinations of anisotropic interactions for determining the torsion angles in peptides are shown in Figure 4. The correlations between anisotropic interactions for N and C^α provide the ϕ angle, and those between interactions for C^α and C′ provide the ψ angle. These methods can be either the DQ/ZQ method or the SQ correlation methods. The information on the ϕ and ψ angles can be obtained from the correlation between carbonyl ^{13}C spins that are separated by three bonds [36,38,43]. The correlation between N–H dipolar couplings was also employed for the torsion angle measurements from their correlation [44,45].

Part I

Telomeric DNA Complexes

Comparison of DNA-Binding Activities Between hTRF2 and hTRF1 with hTRF2 Mutants

Shingo Hanaoka, Aritaka Nagadoi, and Yoshifumi Nishimura
Graduate School of Integrated Science, Yokohama City University, Tsurumi-ku, Yokohama 230-0045, Japan

Abstract

Telomeres are the ends of eukaryotic linear chromosomes consisting of repetitive G-rich sequences and telomeric repeat binding factors. In mammalian telomeres, TRF1 and TRF2 bind to double-stranded telomeric DNA consisting of TTAGGG repeats and regulate telomere length. Both contain a central TRF-homology domain and a C-terminal DNA-binding domain. We have determined the solution structures of DNA-binding domains from human TRF2 and TRF1 bound to a telomeric DNA. Both structures are very close to each other, however, small but significant differences are observed. Based on their structures, we created six mutants of the hTRF2 DNA-binding domain and the DNA-binding activities of all these DNA-binding domains could be well analyzed.

Introduction

Telomeres are protein–DNA complexes that distinguish natural chromosome ends from damaged DNA. Mammalian telomeric DNA is composed of long tandem array of the double-stranded telomeric repeats of TTAGGG followed by a single-stranded DNA at the 3′ end. TRF1 and TRF2 are mammalian telomeric repeat-binding factors [1,2,3]. Although the cellular functions of TRF1 and TRF2 are different from each other, both contain similar functional domains, a central TRF-homology (TRFH) domain and a C-terminal DNA-binding domain [3,4,5], except their N-terminal domains: an acidic domain in TRF1 but a basic domain in TRF2 [2]. Both DNA-binding domains of human TRF1 and TRF2 contain a similar amino acid sequence to each of the three repeats in the c-Myb DNA-binding domain [6,7].

Results

Structures of the hTRF2 and hTRF1 DNA-Binding Domains Bound to a Telomeric DNA

Figure 1 shows a structural comparison between the telomeric DNA-bound structures of hTRF1 [8] and hTRF2 [9]. Each structure contains three helices and these three helices are maintained by a hydrophobic core including three conserved tryptophan residues and also by two salt bridges. Each of three helical architectures in hTRF1 and hTRF2 is a typical Myb motif found in the three repeats of the c-Myb DNA-binding domain [10,11,12]. In both DNA complexes of the DNA-binding domains of hTRF1 and hTRF2, only the single Myb-like domain consisting of three helices can bind specifically to a double-stranded telomeric DNA with a sequence of GTTAGGGTTAGGG (Figure 4). Figure 2 shows a summary of intermolecular contacts observed in both DNA complexes of hTRF1 and hTRF2; each third helix recognizes the middle T3A4G5G6G7 sequence in the major groove of DNA and each N-terminal flexible arm interacts with the following T8T9 sequence in the minor groove [8,9].

Structural Comparison Between the DNA Complexes of hTRF2 and hTRF1

By comparing amino acid sequences of DNA-binding domains, consisting of 438–500 of hTRF2 and the corresponding sequence of 371–433 of hTRF1, 31 amino acids out of 63 amino acids are identical; both DNA-binding domains hold a very similar tertiary structure in their DNA bound forms. So the binding modes as well as the architectures of DNA complexes of both DNA-binding domains are very close in each other.

By clarifying DNA interaction modes of both domains in detail, we have found that four amino acids responsible for the DNA-binding are different from each other, Lys447, Ala471, Ala484, and Arg496 in hTRF2 and the corresponding amino acids, Arg380, Ser404, Ser417, and Lys429 in hTRF1. In the minor groove interaction by the flexible arm of hTRF2, Lys447 contacts only with T9, however, in the hTRF1 complex Arg380 likely interacts with A19, the counter part of T8, as well as T9. Figure 3 shows that in the hTRF1 complex Arg380 contacts both T9 and A19 in the minor groove, however, in the hTRF2 complex Lys447 interacts mainly with T9. It is likely that hTRF1 interacts stronger to the TT portion in the AGGGTT sequence than hTRF2.

hTRF1complex
hTRF2complex

Fig. 1. Structures of telomeric DNA complexes from hTRF1 and hTRF2. (See also Plate 63 on page XLIV in the Color Plate Section.)

In the hTRF2 complex, the amide hydrogen of Ala471 contacts with the phosphate group of T3 (Figure 3). Similarly, in the hTRF1 complex, the amide hydrogen of Ser404 contacts phosphate group of T3. While, the hydroxyl group of Ser404 together with the hydroxyl group of Ser 417 contact with the phosphate group of T3 as shown in Figure 3. This suggests that for the recognition of the phosphate group of T3, hTRF1 has a little stronger activity than hTRF2. Although in the hTRF1 complex Lys429 contacts with the phosphate group of T17, the counterpart of A10, in the complex of hTRF2 the corresponding amino acid, Arg496 is not likely interact with the phosphate group of T17. In this sense also hTRF1 seems to bind much stronger than hTRF2.

To check contributions of four amino acids described above for the DNA-binding activities of hTRF2 and hTRF1, we created six mutants of hTRF2, in which four critical amino acids, Lys447, Ala471, Ala484, and Arg496 are changed into the corresponding amino acids of hTRF1: four single mutants, K447R (2m1), A471S (2m2), A484S (2m3), and R496K (2m4), in which Lys447, Ala471, Ala484, and Arg496 are replaced by arginine, serine, serine, and lysine residues, respectively, one double mutant (2wm), A471S/A484S, in which both Ala471 and Ala481 are substituted by serine residues, and one quadruple mutant, K447R/A471S/A484S/R496K, designated as 24s, in which all four amino acids, Lys447, Ala471, Ala484, and

The Imino Proton Signal Changes of the Telomeric DNA Bound to the hTRF2 DNA-Binding Domain and the Mutants

We have examined the DNA-binding titartions of these mutants by 1-D NMR. Figure 4 shows 1-D NMR spectra of the imino proton signals of the 13mer DNA complexed with the wild type (A) and the six mutants of hTRF2 (B–G), together with the chemical shift changes of the imino proton signals from the free-state to the bound-state. Compared to the wild type in K447R the big chemical shift changes were observed for the imino protons of G7, T8, T9, and T17, the counterpart of A10. This suggests that as found in the hTRF1 complex the substituted arginine residue at 447 in the mutant of hTRF2 could interact with A19, the counter part of T8, as well as T9. Compared to the wild type in the spectra of A471S and A484S small but significant chemical shift changes were observed for the imino protons of T2 and T3, respectively and also A471S/A484S shows both significant changes together with the imino proton shift change of T23, the counterpart of A4. These might be related to the fact that the corresponding two-serine residues in hTRF1 contact with the phosphate group of T3. In R496K no significant chemical shift changes were observed compared to the wild type. In the spectrum of 24S, K447R/A471S/A484S/R496K, significant chemical shift changes of the imino protons were observed in T2, T3 G7, T8, and T9.

The DNA-Binding Activities of hTRF1, hTRF2, and the Mutants of hTRF2

The binding activities of hTRF1, hTRF2, and the six mutants of hTRF2 with the wild-type telomeric double stranded DNA, tr13, and three DNA mutants, T3G, G7C, and T9C as shown in Figure 5 were examined by using a surface plasmon resonance (SPR) apparatus, BIACORE. As expected the binding ability of hTRF1 is about four times stronger than the ability of hTRF2.

For the wild-type telomeric DNA, tr13 almost all mutants of hTRF2 except R496K have stronger DNA-binding activities compared to the wild type, especially the mutant K447R binds to DNA 2.5 times stronger than the wild type of hTRF2. This suggests that the substituted arginine residue in the mutant could interact with A19, the counter

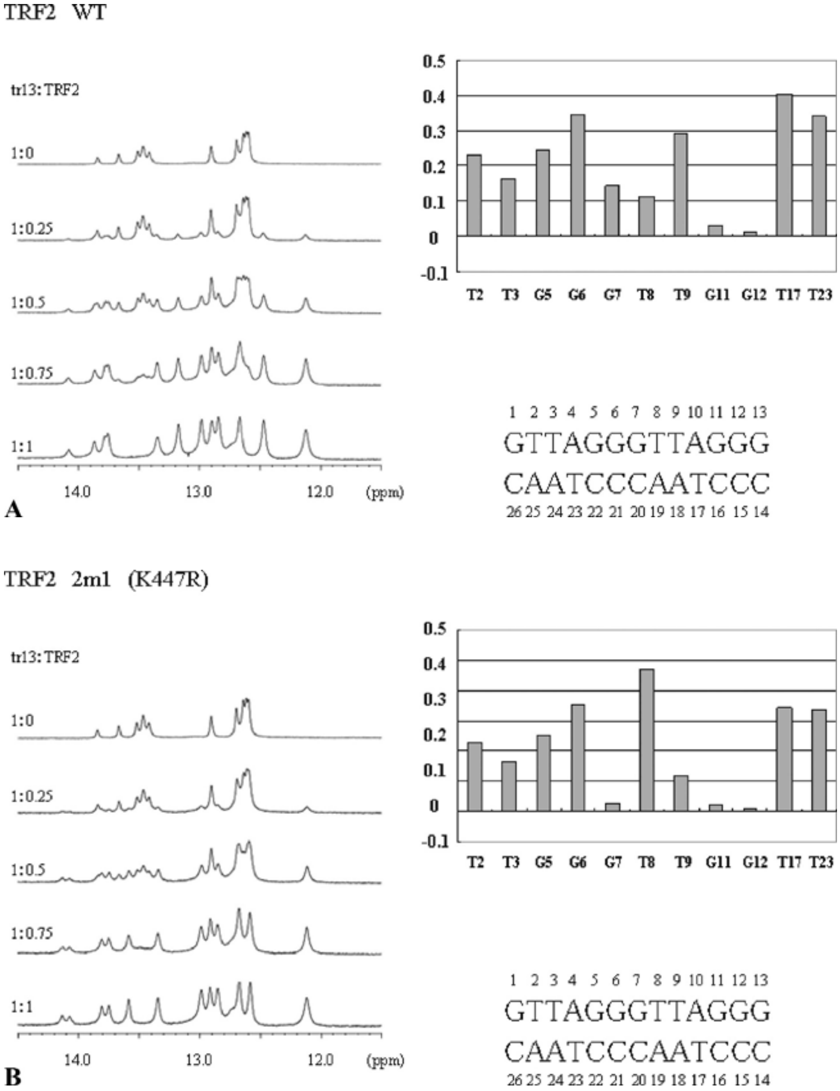

Fig. 4. NMR titration experiments of the wild-type (A), K447R (B), A471S (C), A484S (D), R496K (E), 2wm (A471S/A484S) (F) and 24s (K447R/A471S/A484S/R496K) (G) to the telomeric double stranded DNA together with the summary of the chemical shift changes of the imino proton signals of each mutant from free state to the DNA-bound state.

part of T8, as well as T9 in the minor groove like hTRF1, while Lys447 of the wild type contacts with T9 alone. This is well correlated to the fact that big chemical shift changes of the imino protons of T8 and T9 were observed between the wild type of hTRF2 and K447R. As suggested by the small chemical shift changes of A471S and A484S from the wild type both mutants bind slightly stronger than the wild type. The mutant, 2wm (A471S/A484S) binds to DNA stronger than both single mutants. Serine residues at 471 and 484 seem to bind to the backbone phosphate group independently, like hTRF1. Although R496K showed small chemical shift changes, its binding ability is very close to the wild-type ability; for an amino acid of 496 of hTRF2 both lysine and arginine residues seem to

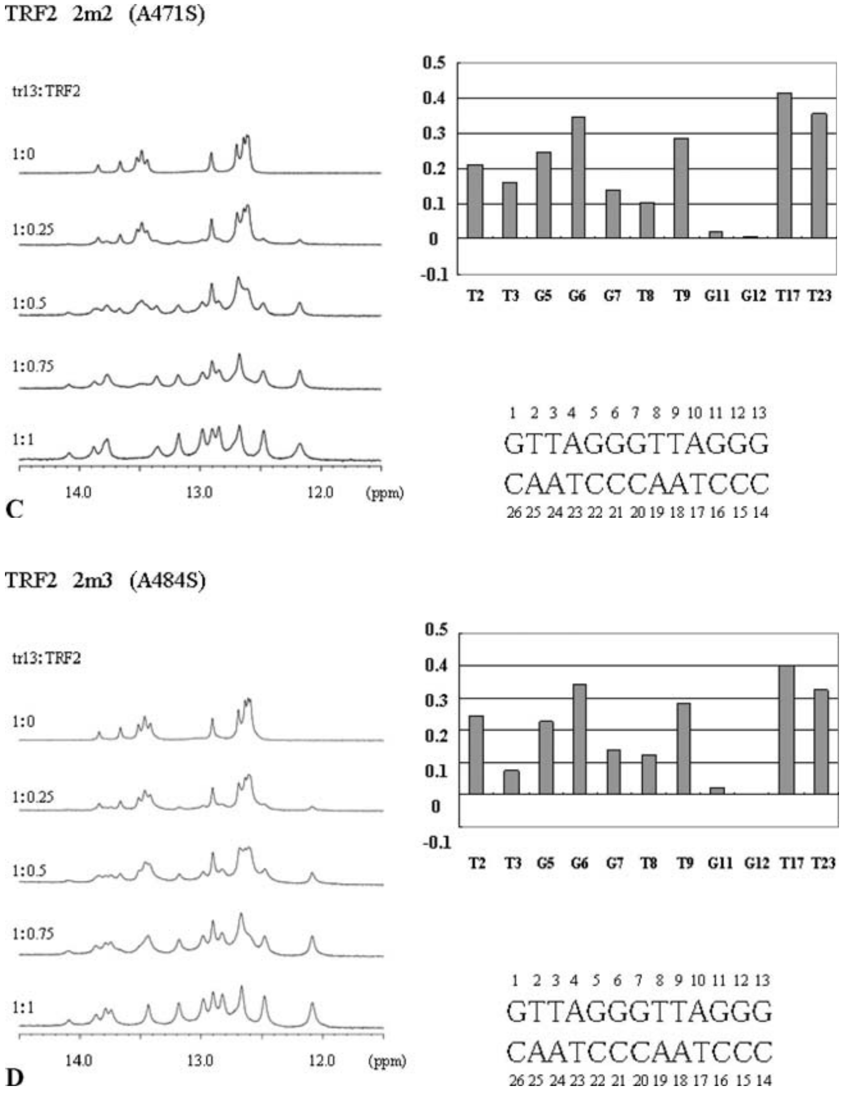

Fig. 4. (*Continued*)

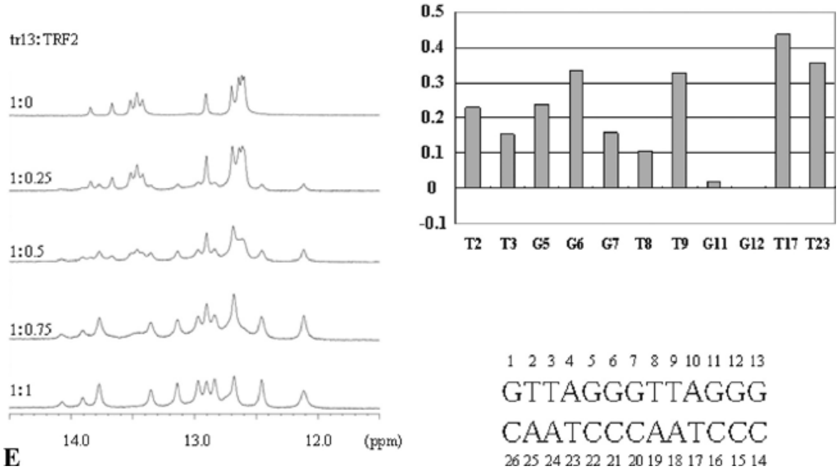
play a similar role in the interaction with DNA. As shown in Figure 3 just a positive charge at 496 of hTRF2 or at 429 of hTRF1 seems to be responsible for the interaction with phosphate backbone.

The mutant, 24s (K447R/A471S/A484S/R496K) binds to DNA stronger than the wild type of hTRF2, with a similar binding ability to the hTRF1 DNA-binding domain. Arg447, Ser484, and Ser496 in 24s likely interact with DNA independently. This may lead to the conclusion that only three amino acids, Lys447, Ala471, and Ala484 of hTRF2 and the corresponding amino acids, Arg380, Ser404, and Ser417 of hTRF1 are critical amino acids that clarify the DNA-binding activities of hTRF2 and hTRF1, because the substitution of Arg496 of hTRF2 to a lysine residue does not affect the DNA-binding ability of hTRF2.

Compared to the wild-type telomeric DNA for the DNA mutants of T3G and T9G the binding abilities of

TRF2 2m4 (R496K)



TRF2 2wm (A471S,A484S)

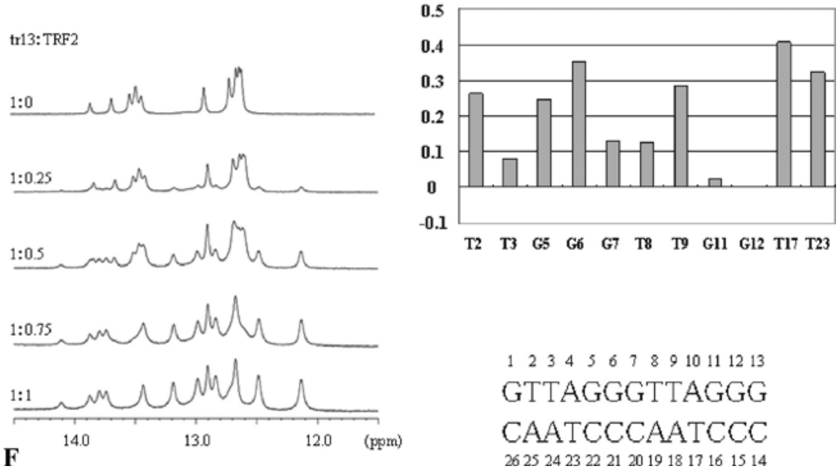


Fig. 4. (*Continued*)

the wild type and the six mutants are reduced, however comparative binding abilities between TRF1, TRF2 and the six mutants of TRF2 are similar as shown in Figure 6. The order of the binding activities for tr13, T3G, and T9G from stronger to weaker are TRF1, 24S, 2m1, 2wm, 2m2, 2m3, 2m4 and TRF2 in all cases. So the discussions stated for the tr13 DNA are likely conserved for the T3G and T9G DNA. In T9G where T9 is replaced by guanine, still T8 exists in the mutant DNA so T8 may have a stronger binding ability to an arginine residue at 447 position of TRF2 compared to a lysine residue at the same position. In T3G the different binding abilities of TRF1, TRF2 and the six mutants are caused by a phosphate at the position of 3 in DNA, so the similar comparative binding modes are observed in tr13 and T3G.

It is interesting to note that in G7C the comparative binding abilities of TRF1, TRF2 and the six mutants are different from their comparative abilities in tr13.

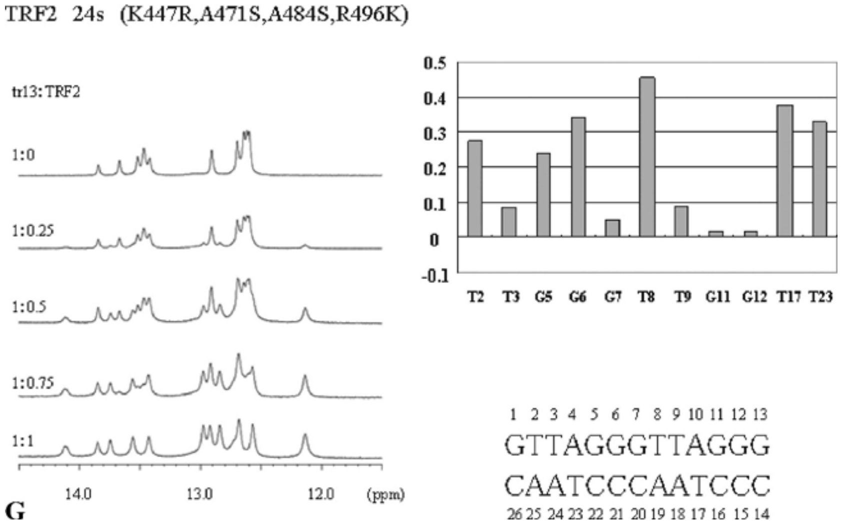

Fig. 4. (*Continued*)

Especially 24s has a similar binding ability with the wild-type TRF2 and the so weaker binding ability than TRF1, in contrast to the cases of tr13, T3G, and T9G. This may be caused by a replaced lysine residue at 496 position of TRF2, because 2m4 shows a weaker binding ability compared to the wild type TRF2. In G7C an arginine residue at 496 may interact with C7 or G20, so the difference of the binding abilities between TRF1 and TRF2 in G7C is not so great compared to the differences in tr13, T3G, and T9G. However, still arginine residue at 381 position in TRF1 is responsible for the stronger binding ability compared to TRF2 in which a lysine residue is located at 447.

Introduction

This chapter discusses methods of optimizing contrast in magnetic resonance imaging (MRI) either by using the intrinsic properties of the tissue or by using contrast agents. In order to fully explain MRI contrast mechanisms, some MRI basic physics will also be discussed. The goal is to provide the tools to set up scans which will best visualize a target tissue or structure.

Physics Background for Contrast Optimization

Signal-to-Noise Ratio (SNR), Contrast-to-Noise Ratio (CNR), and Temporal Resolution

In setting up an MRI experiment, there are several basic questions that should be asked:

1. How much contrast do I need?
2. How much spatial resolution do I need?
3. How much temporal resolution do I need?

These questions will help determine an optimal scan sequence. On animal scanners, which are not quite as “push button” as clinical scanners, the scans will need to be tailored to the experiment. With a good idea of what is wanted and/or needed, the preliminary experiments can be reduced tremendously. As these points are being considered in the experimental design, it is worth recognizing that in MRI there is always a trade-off between signal-to-noise ratio (SNR), spatial resolution, and temporal resolution. As scanners improve technically, the trade-offs decrease, but they still exist and it is wise to recognize and understand why these trade-offs exist. This section will discuss the questions posed above and how to operate within the limitations intrinsic to MRI physics.

As a start, some of these terms need defining and the associated tools explained. These are some of the basic definitions needed to quantify MR images:

- *SNR*: Signal-to-Noise ratio is a measure of the quality of the image. A higher number is better. SNR is equal to the mean of the signal of the region of interest (ROI) divided by the standard deviation (SD) of the background noise (Figure 1).

$$\mathrm{SNR} = \frac{\text{Mean ROI signal}}{\text{SD noise signal}} \tag{1}$$

- *CNR*: Contrast-to-noise ratio provides an indicator of the level of contrast between two tissues/objects. CNR is defined as the difference in mean signal intensities between two ROIs divided by the SD of the noise (Figure 1).

$$\mathrm{CNR} = \frac{\text{Mean ROI}_1\text{ signal} - \text{Mean ROI}_2\text{ signal}}{\text{SD noise signal}} \tag{2}$$

- *Spatial resolution*: The size of the pixel (2D) or voxel (3D). The spatial resolution is the field of view (FOV) divided by the corresponding matrix size. If the image is two-dimensional, then the third dimension is the slice thickness.
- *Temporal resolution*: The time it takes to collect one scan or set of scans.
  Scan time = $T_R \times$ Phase encode matrix size $\times$ Number of averages, where T_R is the repeat time.
- *Pixel*: A picture element, i.e. one point of the image.
- *Voxel*: A volume element, i.e. a three-dimensional pixel element, it has length, width, and height.

Figure 1 provides an example of measuring SNR and CNR. Figures 2 and 3 provide examples of different image resolution.

Although the definitions above are relatively simple, there are several scan parameters that effect SNR, such as:

- FOV;
- slice thickness;
- number of averages;

Graham A. Webb (ed.), Modern Magnetic Resonance, 759–768.
© 2008 *Springer.*

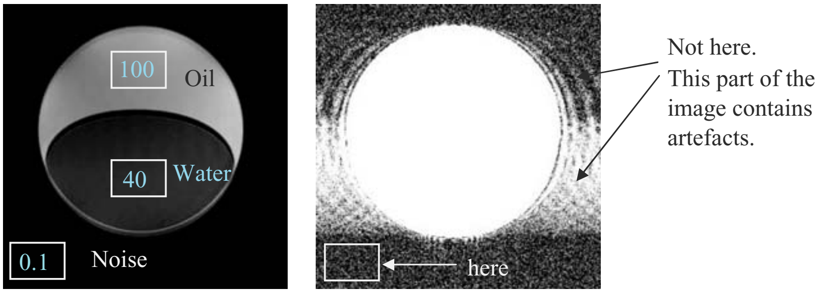

Fig. 1. The left hand image shows a scan of a vial with oil and water in it. The oil is the bright signal at the top and the water is the dark signal at the bottom. The SNR of the oil would be the mean of the signal of all the pixels in the square ROI divided by the SD of the signal of the pixels in the noise. The image on the right shows where to measure the noise (and where not to measure the noise). This image is the same as the image on the left, windowed to a level to show the background noise. It is important to measure the noise in the background noise, and not in signal generated by any image artifacts. Examples: SNR of the oil would be 100/0.1 = 1000, the SNR of the water would be 40/0.1 = 400. The CNR between the water and oil would be: (100 − 40)/0.1 = 600.

- receiver bandwidth;
- matrix size;
- Echo time (T_E), repeat time (T_R), and flip angle (FA).

These factors will affect the SNR in how much magnetization is available. We will assume that these parameters do not vary. Equation (3) gives this in detail.

The basic point to remember is that in the image a voxel describes how many protons contribute to the signal in a given time. If the voxel is decreased by decreasing the FOV, increasing the matrix size, or making the slice thinner, SNR will be lost simply because there are fewer protons in each voxel. If the voxel is increased, SNR will be increased. Similarly if the intrinsic signal within that voxel is altered by changing the T_E or T_R, the SNR will be affected. The hardware will also play a part in the amount of signal that is available, and is discussed briefly later in the chapter.

$$\text{SNR per voxel} \propto \frac{\mathrm{dim}_x\, \mathrm{dim}_y\, \mathrm{dim}_z \sqrt{N_x N_y N_z N_{\mathrm{avg}}}}{\sqrt{BW}} \qquad (3)$$

where N_x is the matrix size in x, N_y is the matrix size in y, and N_z is the matrix size in z. N_{avg} is the number of averages. BW is the receiver bandwidth. The voxel size in the x-direction is dim_x, the voxel size in the y-direction is dim_y, and the voxel size in the z-direction is dim_z. Voxel size is the FOV in a given direction divided by the matrix size in the same direction.

Equation (3) describes the three-dimensional case. If you have a multislice (2D) imaging sequence, then dim_z is the slice thickness and N_z is 1.

Temporal resolution is another issue to consider. For good temporal resolution good SNR at a fast speed is

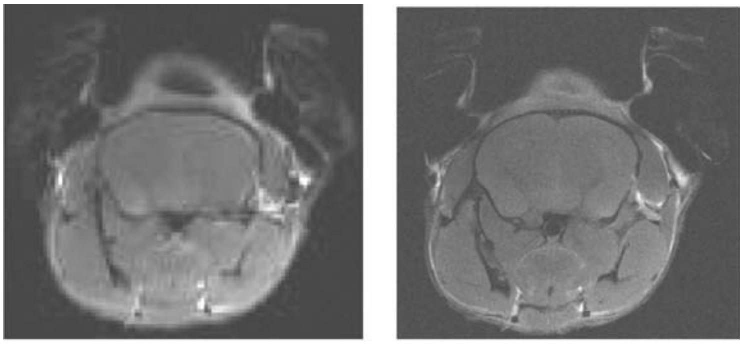

Fig. 2. *Left:* Low resolution scout/pilot image: FOV 30 × 30, matrix 256 × 128, 1 average, 2 mm slice thickness, in-plane resolution of 117 × 234 µm, 2-min scan. *Right:* FOV 30 × 30, matrix 512 × 512, 2 averages, 0.5 mm slice thickness, in-plane resolution of 58 × 58 µm, 25-min scan. Both images are spin-echo with T_R = 1500 ms and T_E = 20 ms.

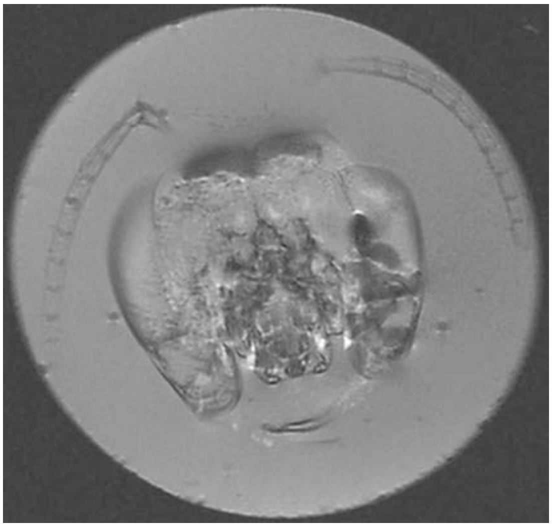

Fig. 3. Transverse image through the head of a bumblebee, fixed in agarose gel. Spin-echo, $T_R = 2000$ ms, $T_E = 20$ ms, FOV 12 mm × 12 mm, matrix 512 × 512, 100 averages, 0.5 mm slice thickness, in-plane resolution of 23 × 23 μm, 30-h scan. A good reference for MRI entomology is Ref. [117]. Image courtesy Dr R. B. Lotto.

required. Do not expect to obtain high SNR and ultra-high resolution if images must be collected in less than 1 s.

A simple rule of thumb for SNR—if the voxel volume is cut in half, then four times the averages will be needed to regain the same SNR. If the voxel is cut down to one-fourth of its original size, then 16 times as many averages will be needed to keep the same SNR. As spatial resolution goes down (i.e. the voxels become smaller), the SNR decreases. In order to counteract this, the BW can be decreased but there will be a hardware limit as to how short the BW can be. The number of averages can be increased too, but as the number of averages goes up so does the scan time and the temporal resolution increases. Typically it will take longer to collect a scan with very small voxel size—simply because the number of averages must be increased to maintain a minimum SNR. Figure 3 is an example of a very high resolution scan.

Very often one of the first questions asked about a new MRI scanner is: what resolution can be achieved? Although this *may* give some sort of benchmark of the strength of the gradients, it is by no means the correct question to ask about how the scanner behaves. It is far more important to know what SNR can be obtained at a given resolution. The gradients may be very strong, but poorly designed radio frequency (RF) coils will mean that although there is the *ability* to collect images at 10 μm, the SNR will be low due to poor RF coil design and the images will be very noisy. At times it is possible and desirable to work at a lower resolution and obtain very high SNR, rather than to work at a very high resolution at low SNR. If the anatomy is not visible because of low SNR then nothing has been gained.

Several groups are developing excellent MRI atlases of the mouse brain, mouse embryo, and full mouse body [1–4]. These provide good examples of different spatial and temporal resolutions. Table 1 provides some typical imaging parameters as starting places for standard anatomical scans.

If high spatial resolution is required, be prepared for significantly longer scan times as more averages will be required to maintain an adequate SNR. From Equation (3), it is obvious that in order to maintain the same SNR when decreasing FOV and matrix size, an increase in the number of averages is required.

Intrinsic MRI Contrast—T_1 and T_2

It is possible to obtain images with good SNRs that do not provide adequate information. If visualizing small structures is needed (such as distinguishing the anterior and posterior pituitary) then another scan technique may be required to improve the contrast between the two tissues. If the two different tissues have different T_1 or T_2 characteristics the sequence can be adjusted to optimize the contrast between the tissues. It may be appropriate to use contrast agents to accentuate one tissue over another.

There are two processes used to describe the basic MRI signal, T_1 and T_2. T_1 is the longitudinal relaxation time (also known as the spin-lattice relaxation time) and T_2 is the transverse relaxation time (also known as the spin–spin relaxation time). T_1 is the parameter that describes the speed at which the magnetization realigns itself with the main magnetic field after the RF pulse has been applied. Figure 4 shows a typical T_1 recovery curve. T_2 is the parameter that describes the speed at which the magnetization dephases in the transverse plane—thus the speed at which the signal decays after the RF pulse (Figure 5). Although this may seem complicated, the point to remember is that the T_2 will indicate the range of T_E values and T_1 will indicate the range of T_R values. For example, if the sample tissue has a very long T_1 (on the order 2 s) then if the scan has a short T_R (e.g. 100 ms), the longitudinal relaxation (governed by T_1) will not have recovered within the T_R and the image will have a low SNR. Using contrast agents to shorten the T_1 (such as gadolinium) will give higher SNR with shorter T_R values. Likewise, if the object has a very short T_2 value (solid tissues have shorter T_2s), then a short T_E will need to be used or the signal will have decayed. For a full discussion of the parameters T_1 and T_2, see Refs. [5,6]. The following web pages also provide good, easily accessible descriptions of T_1 and T_2.

Table 1: Standard scan parameters

Parameter	Whole body mouse at 4.7 T	Mouse brain at 9.4 T	Mouse brain at 9.4 T
2D or 3D acquisition	Multislice (2D)	Multislice (2D)	Volume (3D)
Scan type	Spin-echo	Spin-echo	Gradient-echo volume
RF coil	40 mm ID 100 mm long birdcage	25 mm ID birdcage	25 mm ID birdcage
T_R (ms)	2600	1200	13
T_E (ms)	16	15	4
FA	*	*	20–30
FOV (mm)	45 × 45	25 × 25	30 × 30 × 30
Matrix	256 ×192**	256 × 256	192 × 192 × 192**
Averages	4	4	2
Slice thickness (mm)	2	1	Collected as 192 slices 150 μm thick. Set by the FOV and matrix parameters above
Number of slices	60	30	
In-plane resolution	175 μm	95 μm	150 μm
Time to run scan	33 min	20 min	15 min

* Standard 90/180 flip angles are used for spin-echo scans.

** Zero-filled to 256. The use of 192 as a matrix size in the phase encode direction is a time saving tool, as well as increasing the voxel size which increases the SNR.

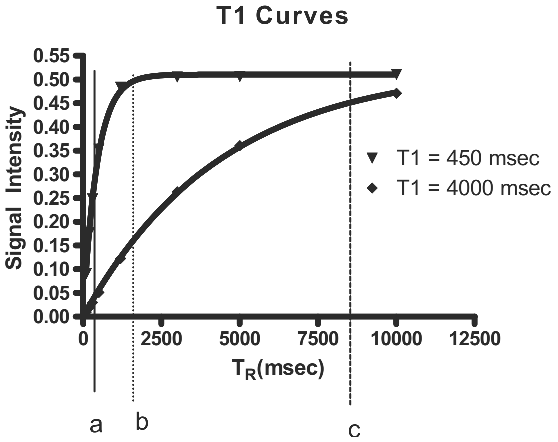

Fig. 4. Example T_1 Plot. This shows two T_1 curves, one with a short T_1 value of 450 ms (triangles) and one with a long T_1 value of 4000 ms (diamonds). The signal for the short T_1 will recover quickly and give a higher signal intensity on scans with short T_R values (imaging at point a on the plot). If you scan with a T_R of approximately 1500 ms (at point b) you will have very good contrast between these two tissues. If you scan with an extremely long T_R (8000 ms) then both tissues will have bright signal.

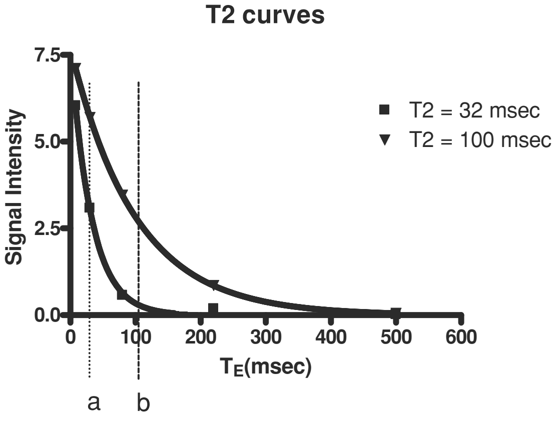

Fig. 5. Example T_2 plot. This shows two T_2 curves, one with a short T_2 value of 32 ms (squares) and one with a long T_2 value of 100 ms (triangles). The signal for the short T_2 will decay quickly and give a lower signal intensity on scans with longer T_E values (imaging at point b on the plot). If you scan with a T_E of approximately 20 ms (at point a) you will have good signal from both tissues.

- http://www.simplyphysics.com/ by Moriel NessAiver

The topic of T_1 and T_2 could be discussed for a very long time, but it is sufficient to recognize that, in general, it is advantageous to know the basic values for the tissue of interest at the field strength of the scanner. As the field strength increases, the T_1 values will get longer. T_2 is relatively unaffected by magnetic field strength. If the objects being scanned are items such as plant matter, the T_1 and T_2 values will almost certainly be significantly different than that of animal matter. T_1 and T_2 will also vary from *in vivo* to *ex vivo*. Table 2 compares human and animal tissue T_1 and T_2 values at different field strengths.

Very often images are described as T_1-weighted (T_1W) or T_2-weighted (T_2W). This will give an indication of the contrast mechanisms (for instance if the signal variations are dictated by T_1 parameters). There is a continuum of scans from proton-density (PD) to T_1W to T_2W, and often it is difficult to know what weighting the image has. In general, short T_R and short T_E will give a T_1W image, long T_R and long T_E will give T_2W image, and long T_R and short T_E will give a PD-weighted image. Borrowing from clinical definitions: a T_1W image will have bright fat and dark cerebral spinal fluid (CSF); a T_2W image will have dark CSF. These parameters can be used to observe physical changes, for example, T_1W images can be used to measure the amount of body fat, and T_2W scans can be used to measure the CSF space in the brain.

There are occasions when simply working with T_1 and T_2 parameters is not sufficient to observe fine variations in tissue structure. When alteration of scan parameters (T_E and T_R or FA) is not sufficient to enhance differences in tissue or to visualize pathological structures, one should consider administering contrast agents. A later section in this chapter goes in to the details of exogenous contrast agents.

Table 2: T_1 and T_2 values for mouse and human tissue at different field strengths

	T_1 (ms)		T_2 (ms)	
Tissue	9.4 T Mouse	1.5 T Human	9.4 T Mouse	1.5 T Human
Brain—gray matter	1900	920	40	100
Brain—white matter	1700	780	32	90
Muscle	2100	890	20	50
Fat	850	260	30	70

Field Strength and Hardware Considerations

When purchasing an MRI system, or considering which research group to collaborate with, the question may arise as to what is the field strength of the MRI scanner. In general, small-bore scanners are built at higher field strengths than clinical scanners. The primary reason for this is that whereas clinical scanners (1.5 or 3 T) operate with resolutions on the order of mm^3, on animal scanners, in order to see equivalent structures, the resolution needs to be on the order of μm^3. Since the signal in MRI is basically proportional to the volume, i.e. the number of protons that are in that volume, by moving to μm resolution the basic signal has just been decreased by an order of 10^9. By imaging at 9.4 T the field strength has tripled from 3 T, but not by a factor of 10^9. Typically one works at as high a magnetic field as possible to regain the SNR lost in the smaller resolution.

Although it is true that the higher the field strength the higher the SNR, there are drawbacks of working at higher field strengths, some of which are: susceptibility artifacts being more exaggerated, dielectric artifacts become an issue, and RF coils are harder to design. It is well worth checking the literature to investigate any imaging issues that might be relevant to the project at high field.

Gradient coil specifications may be another issue to consider. The gradient coil strength will dictate the minimum spatial resolution, the temporal resolution, and maximum gradient strength for scans such as diffusion-weighted imaging. Currently a minimum spec for a gradient coil for an animal system should be 20 G/cm (even this may be limiting for some imaging experiments). Issues will be cost, heat generated by the gradient coil, method of cooling the gradient coil and shim coils. See Ref. [5] for more details.

RF coils are also crucial to the performance of the whole MRI system. Manufactures often supply transmit and receive RF coils. These often have good performance for general imaging, but if a project requires significant SNR, then an RF coil may need to be built which is tailored to the anatomy. Small head coils are frequently built to image the mouse brain. These may be volume coils (if the target is the whole brain) or surface coils (if the target is only a structure at the surface of the brain). Cardiac, spine, or extremity coils may be required for targeting these anatomies. One of the most important issues related to RF coil design is filling factor: how well the anatomy fills the RF coil. If a large RF coil which holds the whole mouse comfortably is available, this may be a good tool for whole body imaging, but it most certainly will give inferior brain images when compared to a short RF coil which just holds the head. An RF coil, which matches the anatomy well, will provide better SNR, and thus better images.

To recap and formally answer the questions initially posed:

- You will need enough contrast to see your tissue of interest (verify the T_E and T_R values are correct, or use exogenous contrast agents).
- You will need enough SNR and small enough voxels to see the details (verify the matrix size and FOV are correct, and then make sure the RF coil is adequate and there are sufficient averages to provide enough SNR. Also verify the T_E and T_R are correct for the T_1 and T_2 of the tissue.)
- You will need enough temporal resolution to see the pharmacokinetic change or change due to flow. To shorten the scan time, consider shortening TR, reducing the number of averages or the size of the phase encode matrix.

For more information on the basics of MRI physics, see Refs. [5,6].

MR Contrast Agents for Animal Imaging Studies

Why MR Contrast Agents?

Of various imaging techniques, MRI has better soft-tissue contrast than other modalities, such as computed tomography (CT) for example; however, it is still necessary to obtain further characterization by enhancing the difference in signal intensity (SI) between lesion and normal tissue or the difference between different tissues (i.e. CNR). Administering MR contrast agents, in addition to field strength of magnet and scanning pulse sequence design, plays an important role by affecting the water relaxation of tissue or changing its susceptibility effect in the magnetic field. Invaluable imaging information can be obtained by proper use of contrast agents. Clinically, MR contrast agent administration has been extensively used since early 1980s in lesion detection, cancer staging, determining vascularity of tumor, assessment of tissue perfusion and viability; it has also become an essential part of contrast-enhanced MR angiography (CEMRA).

Classification and Mechanism of Contrast Agents

T_1 vs. T_2 Agents

Unlike iodinated contrast for X-ray and CT, MR contrast agents cannot be visualized directly. However its effect on SI change can be observed on MR images by changing the tissue's T_1 and T_2 relaxation times. The SI after administering contrast agents is a function of water concentration of the given agent and T_1, T_2 relaxation times of the tissue. There are a large number of MR contrast agents being applied to human and animal work. Basically, these contrast agents can be divided into two categories, namely, the T_1 and T_2 agents. The T_1 agents affect dominantly the T_1 relaxation time, and therefore the difference in SI between different tissues can be highlighted on T_1W images. Paramagnetic ions such as Gd^{3+}, Mn^{2+}, and Fe^{3+} with unpaired electrons belong to this group. The second group, T_2 agents, such as superparamagnetic iron oxide (SPIO) particles, cause significant magnetic susceptibility effects (especially decreasing the T_2 or T_2^* relaxation times) in the tissue where the contrast been taken up. This effect causes loss of SI, and is demonstrated better on T_2W images than on T_1W ones, and especially on gradient-echo (GRE) or echo-planner (EPI) sequences that are more sensitive to the magnetic susceptibility effect than spin-echo sequences.

Non-specific vs. tissue-specific agents

MR contrast agents can also be classified as non-specific and tissue-specific. Initially, non-specific MR contrast, such as the well-known gadolinium chelate, Gd-DTPA, was developed. It stays in the blood stream and extracellular interstitial tissue space for a relatively short time (half-life on the order of 45 min) and then is largely excreted from the body via the kidney and urinary system. It serves well in many clinical conditions as these contrast agents deposit in some pathological conditions that contain extra-large interstitial space. For example, the lesions in the case of various brain inflammation or tumors that compromise the blood–brain barrier (BBB) become strongly enhanced on T_1W images after intravenous administration of Gd-DTPA (Gadopentetate dimeglumine, Magnevist, Schering AG). If the magnet is equipped with an efficient gradient system, non-specific contrast agents are also used to perform contrast-enhanced dynamic MRI and CEMRA. However, in order to enhance the SI of target structures and further increase the lesion conspicuity, specific contrast agents targeting specific tissues or staying in blood circulation for longer time were thus developed.

For example, attachment of a chemical structure to non-specific Gd-DTPA allows the new compounds to cross the cell membrane of some specific tissues, and they thus become tissue-specific. Gd-BOPTA (Gadobenate dimeglumine, MultiHance, Bracco Diagnostics) and Gd-EOB-DTPA (Gadoxetic acid disodium, Eovist, Berlex Laboratories) are examples of hepatocyte-specific T_1 agents. Furthermore, these agents are eliminated by dual excretory routes (renal and biliary), and, therefore, the bile duct system can also be highlighted on T_1W images as well. A manganese-based paramagnetic contrast agent, Mn-DPDP (Mangafodipir trisodium, Teslascan, Nycomed AS), has also been used in enhancement of tissues with active metabolic processes, such as the liver, pancreas, and heart.

Iron oxide particles like SPIO is another group of tissue-specific MR contrast agent. They shorten both T_1 and T_2 relaxation times of tissue. Its dominant T_1 or T_2 effect, blood half-time and distribution to reticuloendothelial system (RES) are variable with the particle or cluster size. Large particles, such as AMI-25 (Ferumoxides, Feridex, Berlex Laboratories), 80–150 nm in diameter, are phagocytosed rapidly by RES (mainly the liver and the spleen) and with dominant T_2 or T_2^* effect; thus they can be regarded as RES-specific agents on T_2W sequences. On the contrary, smaller particles are phagocytosed slowly mainly by lymph nodes and remained in the blood stream longer than larger ones and with less efficient T_2 or T_2^* shortening. Therefore, the small-particle iron oxide or sometimes called ultrasmall superparamagnetic iron oxide (USPIO) agents, such as AMI-227 (Ferumoxtran, Advanced Magnetics), 20–40 nm in diameter, can be used as blood-pool agents by taking advantage of their longer half-life and T_1 shortening effect, although they do have T_2 or T_2^* effect. Ferrixan (Resovist, Schering AG), 60 nm mean diameter, is used as both a RES-specific agent in detecting liver lesions and a blood-pool T_1 agent to characterize the hemodynamics of lesion.

In addition to the tissue-specific contrast mentioned above, by changing the particle size of SPIO or modifying gadolinium-based agents, cell-labeling or receptor-directed MRI techniques and numbers of "smart" MR contrast agents for detecting biological processes are also under intensive research [7–10].

Applications of Contrast Agents in Animal Models

Central Nervous System

Gadolinium Chelates for Focal Lesion Detection. Since most of the brain structures are covered by BBB, gadolinium chelates do not enhance normal brain parenchyma significantly. However, administration of gadolinium-based chelates helps to visualize pathology that compromises the BBB by leaking into extracellular space. Figure 6 demonstrates sclerotic plaques in the cerebellum of a genetically modified mouse with multiple sclerosis. The plaques develop a high signal intensity after intraperitoneal Gd-DTPA injection.

Manganese Chloride for Nerve Tracking and Demonstrating Neuronal Activation. Manganese chloride ($MnCl_2$) is not appropriate for clinical use in human because of its toxicity. However, it is useful for nerve tracking and demonstrating neuronal activation in animal MRI as it is a potent T_1 agent and can cross voltage-gated Ca^{2+} channels and be transported actively along the axon. Several studies have been done successfully to delineate neuronal architecture (Figure 7) and neuronal physiology by this technique, manganese-enhanced MRI (MEMRI) [11–15].

Gadolinium Chelates and SPIO in Brain Perfusion Images. The perfusion-weighted image is a MR technique which can evaluate perfusion at the capillary level. This particular technique can be done by injection of T_1 contrast agent [16]. Both gadolinium chelates and SPIO (such as USPIO) agents can be used for this purpose, although the advantages, disadvantages, pulse sequences, and MR hardware

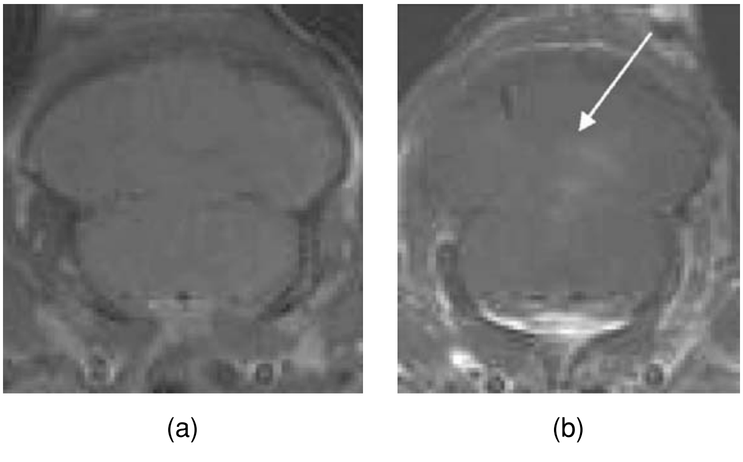

Fig. 6. The spin-echo T_1-weighted images (a) before and (b) after intraperitoneal injection of Gd-DTPA in a transgenic mouse of multiple sclerosis (MS) show significant enhancement over MS plaques (arrow). Images courtesy Drs D. Altmann and S. Ellmerich.

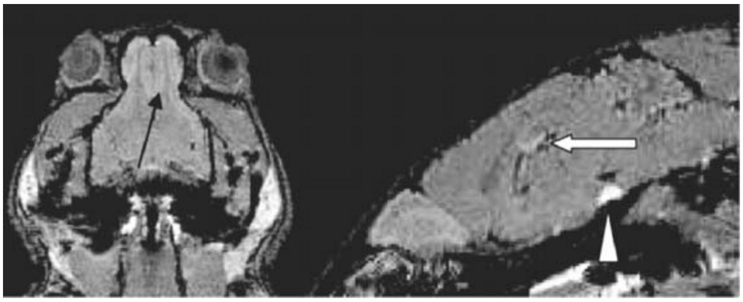

Fig. 7. The 3D FLASH T_1-weighted acquisition with coronal (A) and sagittal (B) reconstruction images of a C57BL/6 mouse after intravenous infusion of $MnCl_2$ show normal layering structures at both sides of the olfactory bulb (black arrow). Also noted is the intense enhancement of the pituitary gland (arrowhead) and choroid plexus in lateral ventricle (white arrow).

requirements for them are different. Several studies with this technique and contrast agents have been done to evaluate neural pathologies such as stroke in animal models [17–19].

Cardiovascular System

Gadolinium Chelates for Heart Imaging. Both in animal models and in clinical human work gadolinium chelates have been used not only in evaluating perfusion of myocardium during the first-pass of the contrast agent on T_1W images but also in depicting the scarred myocardial tissues after infarction on the delayed images [20–23]. Owing to relatively unlimited FOV coverage of heart by MRI (as compared with echocardiography) and the use of contrast agent, contrast-enhanced MRI has become an increasingly important modality to evaluate cardiac pathologies [24,25]. MR techniques have also successfully provided opportunities for cardiac intervention through specially designed catheters and through monitoring therapeutic effect [26]. Also thanks to the development of contrast labeling technique, MRI is able to help the delivery of stem cell therapy in animals by visualizing iron-labeled mesenchymal stem cells [27,28].

Manganese-based Contrast in Determining Viable Myocardium After Infarction. The myocardial enhancement mechanism of manganese-based agents is different from that of gadolinium agents. Manganese agents are taken up by viable myocardium that contains active Ca^{2+} channels; however, gadolinium agents are leaked to the interstitial space due to cell disintegration. Evidence shows that gadolinium also diffuses into oedamatous areas after an infarction, which results in an overestimation of the infarction size [29]. The timing for gadolinium-enhanced MRI to accurately determine the infarction size is also critically important [30]. In a comparative study, manganese-based contrast agents were more accurate in determining the infarct size than gadolinium-based agents [21]. The concerns of manganese agents are its toxicity and competitive nature with calcium ion, which may cause negative inotropic effect to the heart at risk of ischemia. Also because of this nature, in animals, MEMRI also provides the chance to survey the inotropy of the heart [31]. In a recent study, manganese-based contrast was even able to depict the reversible functional deficit of myocardium after episodes of brief ischemia [32].

Gadolinium Chelates and Iron Oxide in CEMRA. Both gadolinium chelates and compounds containing iron oxides have been successful in depicting animal major vascular structures *in vivo* on MRI [33–35]. The main difference between the two groups of contrast agents is that most of the extracellular gadolinium chelates remain in the blood vessels for a relatively short time; USPIO stays in circulation for longer period. Consequently, CEMRA relies on first-pass T_1 shortening effect when using extracellular gadolinium chelates; on the contrary, USPIO as blood-pool agents provide a wider temporal scanning window.

Oncology

Gadolinium Agents in Evaluating Tumor Angiogenesis. Understanding tumor angiogenesis is important to access the pathophysiology of various malignant lesions. Blocking angiogenesis is one method of modern cancer treatment. Detecting or quantifying angiogenesis noninvasively and *in vivo* is attracting increasing interest in cancer research. Gadolinium chelates not only successfully depicted major vascular vessels on MRI, but can also be modified chemically into larger polymers, capable of surveying angiogenesis in certain animal models [33]. By exploiting contrast-enhanced MRI techniques, monitor and guide anti-angiogenetic treatments have been feasible in some studies [36]. The accuracy of MRI in detecting angiogenesis by using different contrast agents is under active investigation.

Targeted SPIO in Detecting Tumor Necrosis (apoptosis). MR spectroscopy (MRS) has been able to depict the biochemical information of tissue and is thus able to identify the apoptotic part of tissue. However, MRS is still not sensitive and lacks of high spatial resolution images when applied *in vivo*. Zhao *et al.* found that *in vivo* MRI was able to detect apoptotic cells of malignant tumor under chemotherapy at early stages by using the conjugation of SPIO and a specific protein called synaptotagmin I [7]. This achievement further expands MRI in the field of oncology by visualizing specific parts of malignant lesions in high spatial resolution MR images.

Conclusion

With the tools described in this chapter, it is possible to begin designing imaging protocols to visualize normal and abnormal structures with MRI. Depending on the area of research one may only need to have anatomical images, where a standard MR scan will be sufficient, but if one needs to track the progression of tumor growth, brain lesion activity or more complicated targets, then exogenous contrast agents may make the job, not only easier, but also possible.

As new contrast agents are being developed for the field of molecular imaging, the area of imaging with contrast agents will be expanding. It may soon be possible to target a contrast agent to specific tissues providing exquisite specialized images of single nuclei of the brain.

The Application of *In Vivo* MRI and MRS in Phenomic Studies of Murine Models of Disease

Po-Wah So and Jimmy D. Bell
Molecular Imaging Group, MRC Clinical Sciences Centre, Hammersmith Hospital Campus,
Imperial College London, London W12 OHS, UK

Introduction

The genomic revolution has rapidly expanded in recent years from unravelling the human genome to sequencing the genome of many other species, including, mice, insects, and plants. Determining the role of individual genes in the pathophysiology of many human and animal diseases has now become a reality. A variety of *in vitro* methods have been developed to assess gene expression at both the cellular and organ levels, allowing ever increasing understanding of the genetic control of disease development. However, it has also become clear that to fully understand the role of many genes in health and disease, it is necessary to determine their function in the context of a whole functioning organism. Indeed, a number of studies have recently shown that the relative expression of some candidate genes is significantly modulated not only by environmental factors but also by the genetic background of the organism [1]. However, the currently available *in vitro* techniques cannot be readily applied to developmental or longitudinal studies, thus limiting their usefulness in elucidating gene expression and function.

This has necessitated the development of non-invasive techniques that can allow the detection and quantification of gene expression, function, and modulation *in vivo*, including positron emission tomography, bioluminescence, and magnetic resonance imaging/spectroscopy (MRI/MRS). Further, the exponential increase in the number of murine models available for basic research over the past 5 years, has spurred an extraordinary interest in methods for objective and accurate phenotyping. Non-invasive imaging techniques are therefore at the forefront of current biological and clinical research and are likely to play a pivotal role in the post-genomic era. In this chapter, we describe the key areas of pre-clinical research where MRI and MRS are being applied, together with those areas, which are likely to become important in future translational research.

A schematic description of the MR approach to phenotyping murine models is illustrated in Figure 1. The strategy can be broadly divided into MRI- and MRS-based techniques. Combination of these two MR techniques in the phenotyping protocol produces an accurate characterization of a whole animal or individual organs.

Magnetic Resonance Imaging

MRI allows non-invasive and three-dimensional visualization of the whole body and structures within the body such as internal organs, providing both highly accurate qualitative and quantitative data. MRI is possible with a variety of nuclei, ^{1}H, ^{19}F, ^{31}P, ^{23}Na but ^{1}H MRI is most commonly used and is assumed in this chapter unless otherwise stated.

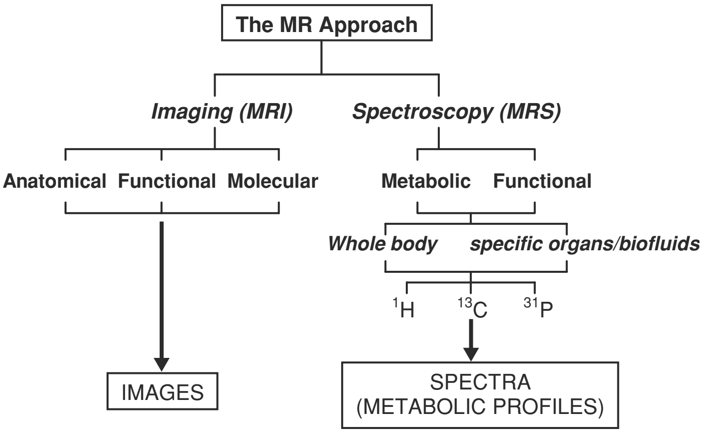
The image quality achieved with MRI represents a compromise between imaging time (sampling duration) and multiple factors that affect spatial resolution. Factors affecting resolution include tissue water content, pixel size, receiver coil size, sampling bandwidth, magnetic field strength, and pulse sequence design. For example, at 9.4 T, employing a customized radio-frequency transmit/receive bird-cage coil of 25 mm diameter, a standard spin-echo sequence with repetition time (TR) of 1500 ms and echo time (TE) of 20 ms, will yield 136 μm in-plane resolution and 0.5 mm slice thickness in ∼2 min, whereas a scan of ∼5 h duration can provide resolution as high as 68 μm in-plane resolution with 0.5 mm slice thickness (Figure 2). Hence, the term "magnetic resonance histology" (MRH) [2], referring to the use of MRI to characterize tissue structure approaching resolutions achievable by histological methods has become a reality. Small animal MRI and MRH tend to be used interchangeably although strictly speaking the latter refer to images acquired with spatial resolution of less than 100 μm in at least two dimensions. There are many excellent review articles describing the evolving MR technology, MR physics, and hardware design for MRH [2–5], and the readers are referred to these for further details.

Magnetic Resonance Histology

In general, during MRH scanning, tissues are preserved either by direct immersion in fixative or fixed *in situ* by

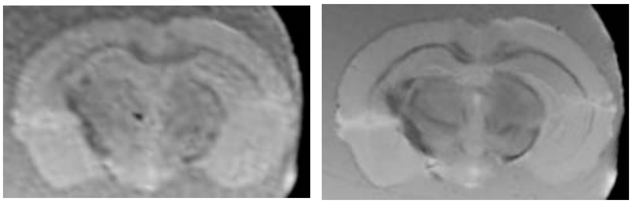
Graham A. Webb (ed.), Modern Magnetic Resonance, 769–785.
© 2008 *Springer.*

Figure 1. Overview of the phenotyping protocol using MR methodology.



intravascular perfusion of fixative, with or without supplementation with MR contrast agents. Specimens may be wrapped in a soft, water impermeable film for MRI [6,7]. Alternatively, the organs may be immersed or embedded in a medium, which would overcome susceptibility artifacts arising from tissue–air interfaces. Ideally, the medium should prevent dehydration and decomposition of the sample; have no ^{1}H signal; be non-toxic and sufficiently viscous to prevent motion of the sample during scanning. Media used include perfluoropolyether or Fomblin [8,9]or a semi-solid substance, e.g. 1% gelling agar [10], 3% agarose [11], 1% agarose gel doped with magnetite or fluorocarbon [12]. Note that formalin is generally avoided as an embedding medium, as it has a strong MR signal leading to difficulties in discerning the specimen surface. Of the embedding media options available, the use of Fomblin or fluorocarbon is near ideal, as neither have ^{1}H nuclei, and both are non-toxic, non-flammable, and prevents dehydration and decomposition of the specimen for up to 2 days [13].

To maximize the value of MRH, MRI has been improved by the introduction of high magnetic field strengths, improved encoding strategies, and specialized radio-frequency receiver coils [14–17]. This has lead to the production of images with exquisite anatomical detail, visualized non-destructively, and producing data in a 3D format. Thus, the disadvantages of serial sectioning required for conventional histological methods, including dissection of the sample, distortion and misalignment of slices during computer registration, and difficulty in automation, can be avoided [18]. It is important to point out that although image resolution can be improved by employing higher magnetic field strengths, this is not without some drawbacks. With higher field strengths, there is an increase in the difference between the resonance frequencies of water and fat, the major components of the body, leading to greater chemical shift artifacts. At 4.7 T, the artifacts are minimal but at higher fields, the artifacts are significant due to greater difference between the water and fat resonance frequencies at higher fields (Figure 3). Such artifacts may be removed by performing MRI with saturation of the water or fat signal leading to a fat-only or water-only image.



Scan time (mins)	2	300
Number of averages	1	40
Resolution (μm)	136	68

Figure 2. Midtransverse MRI images of the brain of a C57BL/6J mouse embedded in 1% agarose at different resolutions obtained at 9.4 T (TR/TE, 1200/20 ms; field of view, 35 mm × 35 mm; 256 × 128 matrix size and zero-filled to 1024 × 1024).

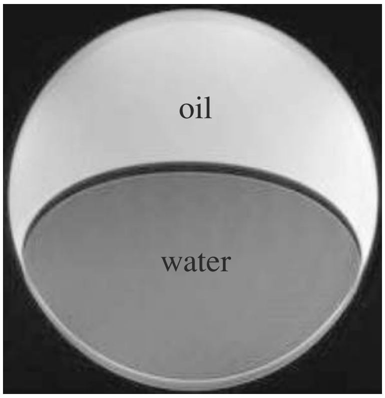


Figure 3. Chemical shift artifact in the MRI image at 9.4 T from a sample containing oil and water. The oil is shifted upwards in the image and note that even the small layer of oil around the edge of the sample has shifted up as well. The black band in the middle is a signal void where the oil has shifted away from the water.

Resolution and SNR are not the only criteria for successful imaging. Signal differences must exist between different structures for their delineation in the MR image, i.e. an adequate contrast-to-noise ratio between/within tissue(s) is required. MR techniques are unique in that several contrast mechanisms, including T_1, T_2, diffusion, etc., with or without the use of contrast agents may be employed. Thus, a mixture of MRI sequences may be enlisted to fully characterize morphology of the whole body or individual organs. However, with the advent of ultra-high field strength systems, further research is required to understand and exploit the alteration in T_1 associated with higher field strengths to enhance the morphological information obtained.

An alternative method to increase resolution while maintaining SNR, is to collect three-dimensional volumes data-sets (3D MRI), which involves collection of volumes rather than the routine 2D-multislice dataset. However, obtaining 3D volumes requires the use of 3D encoding, resulting in large image arrays. The greater the resolution required, the greater the image array produced. Thus, computers of sufficient memory and disk space are required to accommodate and reconstruct the large datasets, e.g. the raw data for a 512 μm × 512 μm × 512 μm image array is 1 Gb with reconstruction time of 1 h [19]. Thus, an important consideration in phenomic studies is the development of computational methods to deal with the vast amounts of data generated.

Phenomics

As well as anatomical data, MRI can provide functional and molecular information. Functional data can be provided by functional MRI (fMRI) principally in the brain or through the use of contrast agents such as manganese chloride ($MnCl_2$). The former has been used for dynamic assessments of phenotyping murine models [20,21] while the potential of the latter has yet to be fully explored. The use of MRI to explore molecular events is in its infancy compared to the other imaging modalities and remains to be developed in terms of phenotyping murine models and will not be further discussed in this chapter (see Chapter VIII). The use of MRI for morphogenic assessment is detailed below. Its use for functional assessment of organs is also detailed below with the exception of fMRI which is detailed in Chapter VI. Thus, aside from 3D depiction of the whole body or organs, and so, morphological representation of murine models, MRI can provide extra dimensions arising from temporal resolution, function, or molecular assessments.

Whole Body Phenome

Phenotyping of the whole body can be achieved readily by using lower magnetic field strengths of, e.g. 4.7 T. However, transmit/receive radio-frequency coils are required with high homogeneity over a sufficient area to encompass a whole mouse. Consecutive transverse images (1 mm thick or less) of the whole body of a mouse can be obtained in ∼15 min with in-plane resolution of up to 100 μm. T_1-weighted imaging using standard spin-echo sequences can generate images from which anatomy/morphology of organs may be adequately observed and measured. The choice of TR and TE determines the contrast (and signal intensity) of the various organs, e.g. TR/TE of 2200/20 ms at 4.7 T, leads to increased contrast between adipose tissue (AT) and adjacent muscle with the former being the more intense. Such TR/TE provides sufficient contrast between individual tissues to allow the delineation of individual structures. By MRI, organs are readily visualized *in situ*, within the 3D framework of the mouse body, enabling the relative spatial geometries of organs to be readily discerned, which is not possible by normal histological methods.

A typical sagittal image through the center of the mouse is shown in Figure 4, with the spine readily discernable along the dorsal side of the mouse. Detailing the structures from nose-to-tail, the eyes (Figure 4a) and brain (Figure 4b) are major organs dominating the images of the head region. On the smaller scale, just visible, are thicker areas of the external ear flaps (Figure 4c). Past the neck, the forelegs are the next major feature visible (Figure 4d), followed by the lungs located within the thorax (Figure 4e). The lungs appear as low intensity areas due to the low density of lung water protons (see below). Occasionally, the heart may be discerned in the thoracic cavity, this occurs when the TR chosen is such that the acquisition coincidently occurs during one of

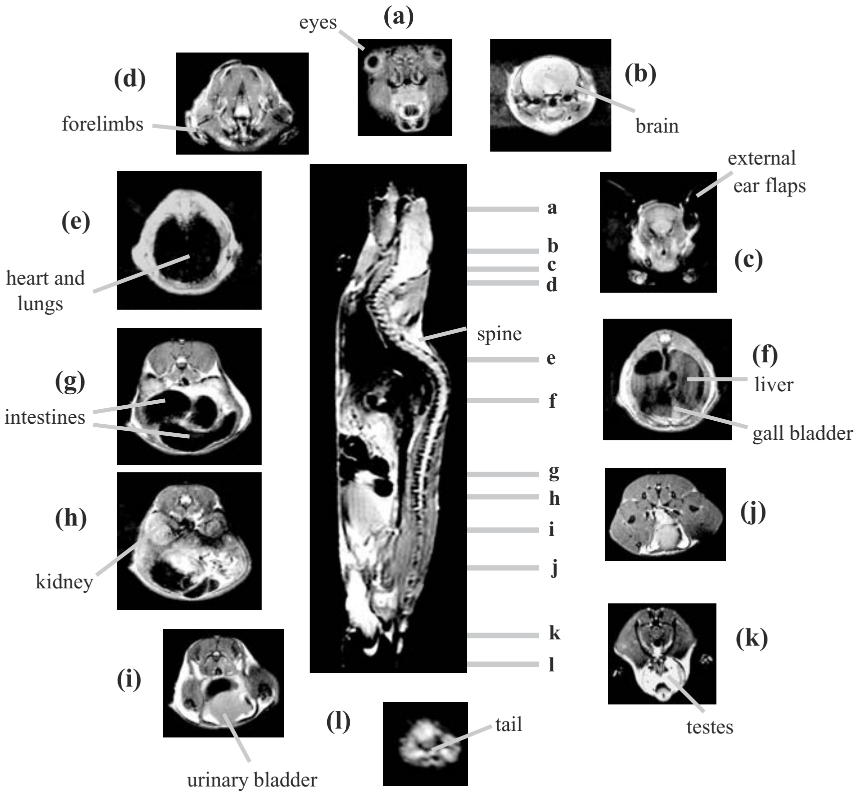

Figure 4. A midsagittal MRI image of a C57BL/6J male mouse and selected transverse MRI images obtained at 4.7 T (TR/TE, 2200/20 ms; matrix size, 256 × 256; field of view, 45 mm × 45 mm; two averages).

the more static phases of the cardiac cycle. Otherwise, signals from the heart are smeared over the image due to its rapid motion (Figure 4e). While it is possible to acquire data by "*cardiac gating*," this is a more involved procedure and requires more specialized and expensive equipment, and an increase in the overall scanning time. Therefore, it is not often performed unless necessary for cardiac phenotyping (see Chapter VI). Just below the lungs is the liver which appears semi-intense in the MRI images (Figure 4f). An empty gall bladder is not readily discerned but if filled with bile (e.g. after fasting), the gall bladder is revealed as a high intensity structure (Figure 4f). Filling the abdomen below the liver are the intestines, they are normally difficult to discern, as their intensity are non-uniform, being dependent on the contents of the intestine at any given location (Figure 4g). Thus, areas of no signal may be seen arising from intestinal gas, and areas of high intensity, from dietary fat as well as areas of intermediate intensities arising from non-fatty substances from food. Fasting of the animals prior to phenotyping render the intestines easier to discern in the MRI images. If phenotyping is performed post-mortem, there may be increased areas of low signal arising from generation of gas from intestinal bacteria following death. While the outlines of the intestines are difficult to distinguish, the lower gastrointestinal tract is readily observed in consecutive transverse slices in the lower abdomen (Figures 4i–k). In the lower abdomen are the kidneys of which the medulla and cortical regions are readily discerned in the MRI images due to differences in their signal intensities (Figure 4h). Distal to the kidney is the bladder which occupies a central location on the ventral side of the lower abdomen (Figures 4i and 4j). The urinary bladder is readily observed when filled with urine due to the high signal intensity of urine. The testis is another organ that can be readily identified in the lower abdomen of male mice (Figure 4k). At the rear of the mouse, the whole of the tail is seen and detailed tail structure observed (Figure 4l). The spine can be observed in successive transverse MRI images but is more readily observed along the length of the mouse, on the dorsal side, from sagittal MRI images. The orientation of scanning is usually determined by the organs of interest but becomes irrelevant if data is obtained isotropically. Obtaining such qualitative and quantitative data in less than 15 min in live mice renders MRI an attractive phenotyping tool for monitoring the effect of environment on the pathophysiology of disease, especially if the murine models are rare and/or difficult to breed. Furthermore, there is also the possibility of *in utero* phenotyping of mice using MRI, to monitor developmental changes at an early stage [22].

Of course, as previously discussed, MRI can be used to phenotype mice post-mortem, enabling higher resolution images to be obtained since sampling time can be extended. Johnson *et al*. [19] performed whole body phenotyping of mice with isotropic 3D spatial resolution of 110 μm × 110 μm × 110 μm and imaging time of 14.5 h at 2 T (Figure 5). The body of the mouse was perfusion fixed with a fixative such as 10% buffered formalin. However, by perfusing with a fixative supplemented with a contrast agent such as GdDTPA (gadopentetate dimeglumine), the SNR could be increased six-fold by decreasing the effective T_1 of the tissues [19]. MRH of embryos has also been performed following catherization of the umbilical vein and perfusion-fixation of the embryo with both fixative and contrast agent [6,8,23]. Indeed, there has been significant progress towards the generation of a microMRI atlas of mouse development [12,24,http://mouseatlas.caltech.edu/13.5dps/]. However, perfusion-fixation can be difficult to perform. Dhenain *et al*. [12] was able to image major organs without the need for perfusion-fixation, although image acquisition time took 36 h per embryo. More recently, by employing a T_1-weighted gradient echo sequence, Schneider *et al*. [25] was able to phenotype paraformaldehyde fixed wildtype and transcriptional coactivator *Cited2* lacking embryos with isotropic resolution of 25 μm × 25 μm × 26 μm in 9 h.

Large scale, genome wide mutagenesis programmes, have led to the creation of many murine models. To facilitate the phenotyping of such large numbers of mice, scanning of several mice simultaneously has been proposed. Bock *et al*. [26] have demonstrated the feasibility of simultaneous whole body MRI from four mice, obtaining data with minimal artifacts. More recently, Dazai *et al*. [27] have developed a multiple mouse loading and monitoring system for MRI of seven mice simultaneously, involving ECG and temperature monitoring.

So far we have described gross anatomy with respect to the whole body; the use of *in vivo* MRI to study the anatomy of individual organs is detailed below:

(a) Brain

MRI has been used to provide detailed morphological features of wildtype and transgenic mouse brains *in vivo* (Table 1), including the outline of all major anatomical regions such as the neocortex, corpus striatum, hippocampus, thalamus, and cerebellum. *Ex vivo* MRI of the fixative-preserved brain allow images of higher resolution (~2.4×10^{-4} mm^3) to be obtained (Figure 6, [37]). Using the C57BL/6J mouse as a test bed, different MR contrast parameters, voxel sizes, SNR, and use of contrast agents were investigated for visualization of the brain by MRH [9]. T_2^* MR images revealed several gross anatomical structures whereas diffusion-weighted proton images were superior for delineating subregions of the hippocampus. The use of contrast agents facilitated the visualization of the hippocampal regions in the T_2^* MR images [9]. Due to the fact that $MnCl_2$ leads to enhancement of specific areas of the brain [38–40], it has recently been used to aid the delineation of certain brain features [41]. Neuroarchitecture can also be defined by fMRI, i.e. following

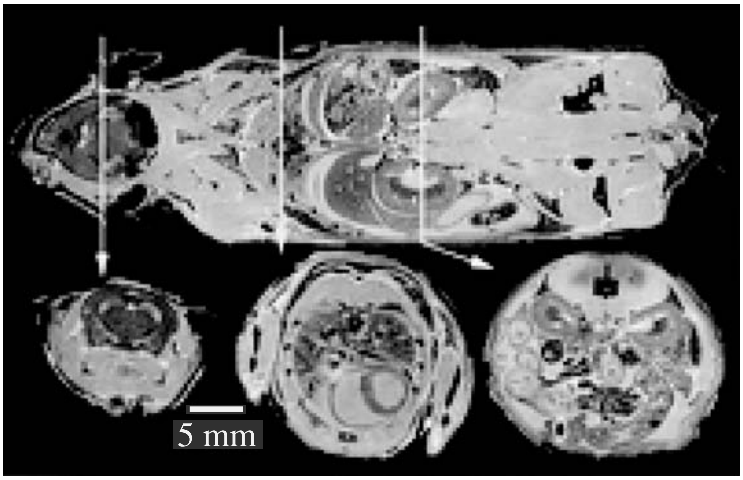

Figure 5. Three-dimensional MR microscopic images with an isotropic array (256 × 256 × 1024) were acquired in a whole fixed C57BL/6J mouse. The spatial resolution in every plane is 110 μm× 110 μm × 110 μm, which allows one to view any arbitrary plane with equal spatial resolution. Coronal (top) and transverse (bottom) images depict 110 μm thick sections of the head (left), thorax (center), and abdomen (right). (Reproduced courtesy of G. A. Johnson, Duke Center for *in vivo* microscopy [19].)

appropriate stimulation, changes observed by fMRI can aid the definition of regions associated with the visual and motor cortex, ocular dominance columns, ocular orientation columns, rodent whisker barrels, rodent olfactory glomeruli, and cortical layers (see Chapters III and IV). The use of MRH for determining brain morphology has been reviewed by Kooy *et al.* [42], and Benveniste and Blackband [17], and the reader should refer to these for further information.

Currently, there are two web-based digital mouse atlases based on MRH data. The "mouse atlas project" (MAP)—which is still under development—consists of four different image modalities—Nissl stained brain sections, MRH data, cryo data, and labeled sections, from the Laboratory of Neuroimaging at UCLA (http://www.loni.ucla.edu/MAP). The other brain atlas website is an atlas of the developing mouse brain (http://mouseatlas.caltech.edu/13.5dps/) from the Biological Imaging Centre at CalTech [12]. A 3D MRI "variational" atlas of mouse brain has recently been published [43]. The concept is to combine multiple 3D images to produce a mouse brain with average anatomy and range of anatomical variation within a particular population, thus allowing the formal quantification of the anatomical variability within a mouse strain, and hence, between mouse strains, especially relevant for phenotyping.

(b) Adipose tissue

Measurement of body AT content and distribution is fundamental to the study and management of obesity. Accuracy can be achieved by chemical carcass analysis but although possible in some animal studies, it does not allow serial measurements to investigate developmental changes and the effects of interventional treatments. MRI can be used to directly visualize, and hence, measure the location and quantification of soft tissues, such as AT and its different depots. MRI as a method to measure AT has been fully validated in animals. In rats, Ross *et al.* [44] compared MRI with computerised tomography (CT) against chemical analysis methods to measure AT and skeletal muscle volumes. Both MRI and CT assessments of AT volume showed comparable accuracy to chemical analysis, the latter being the "gold standard." MRI measurement of AT has also been validated in lean and obese pigs [45], showing excellent correlation with *in vitro* methods. Ishikawa and Koga [46] used MRI to measure abdominal fat and other specific organs in Otsuka Long-Evans Tokushima fatty rats, while Tang *et al.* [47] utilized MRI for longitudinal studies in rats. Subsequently, Changani *et al.* [48] used serial MRI to monitor differences in visceral, subcutaneous, inter-muscular, and total fat distribution between normal mice and a known transgenic lean mice strain over a period of 6–18 weeks. An increase in the various fat deposits and total fat content was observed in the wildtype compared to the transgenic lean mouse. A complete absence of subcutaneous AT and a reduction in other AT deposits were observed by MRI in a mouse model with complete genetic ablation of corepressor protein RIP140 [49]. Today, MRI is therefore the technique of choice for the *in vivo* assessment of AT content and distribution in animals, especially where *in vitro* methods are impractical.

(c) Lungs

The combination of low proton density (lungs mostly consist of air), high susceptibility effects, cardiac and respiratory movements normally associated with the lungs have made it one of the most difficult organs to be imaged *in vivo* by MRI. Indeed, most MRI research, previous to the introduction of hyperpolarized gases, concentrated on imaging lung tumours and inflammatory responses [50–52]. Furthermore, most of this work was carried out in rats, with little work on murine models, where the problems caused by cardiac and respiratory movements are much more severe.

Typical images of the lungs from a normal mouse can be seen in Figure 4e. Due to the low proton density, short T_2, and local inhomogeneities, the lungs appear dark in MR images, greatly limiting its usefulness. Development of non-standard acquisition techniques have gone some way in improving parenchymal tissue imaging but even this has been of limited use. It was only with the introduction of hyperpolarized noble gases (^{3}He and ^{129}Xe) that proper pulmonary MRI was achieved. Since its introduction, hyperpolarized gas MRI has been used successfully to generate information on ventilation of the lung, pulmonary diseases and lung development [53]. Despite these advances, and partly due to costs and availability of hyperpolarized gases for MRI, studies are limited to a very small number of specialized groups, and therefore the potential of this technique has not been fully exploited. However, hyperpolarized pulmonary MRI is likely to become the technique of choice in pre-clinical and clinical research, including morphological imaging of airways and alveolar spaces, estimating absolute airspace size, analysis of the intrapulmonary distribution of the tracer gases, local broncho-alveolar dimensions, and regional broncho-alveolar pO_2 [54,55].

As an alternative to the use of hyperpolarized gas for imaging lungs, inert fluorinated compounds such as perfluorocarbon (PFC) and emulsions of PFC have been considered, using ^{19}F, rather than the conventional ^{1}H nuclei (Figure 7). PFC and PFC-water emulsions are used to assist ventilation in acute respiratory distress syndrome and are readily available. Furthermore, the fact that oxygen can modulate the T_1 relaxation properties of the fluorine in PFCs, has been utilized to measure lung pO_2 *in vivo* [56–58]. This suggests that PFCs can be used for simultaneous analysis of lung structure and pulmonary oxygenation patterns.

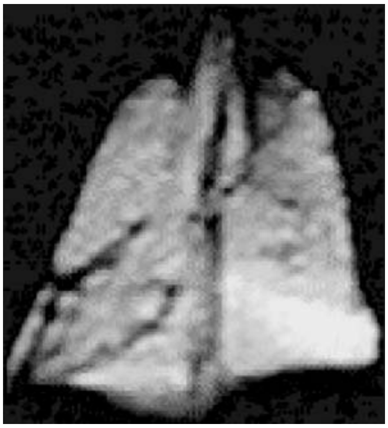

Figure 7. A midcoronal ^{19}F MRI image of PFC filled lungs of a C57BL/6 mouse obtained on, at 9.4 T, MRI scanner (TR/TE, 1000/20 ms; FOV, 100 mm × 100 mm; matrix size, 256 × 256, two averages, 2 mm slice thickness).

(d) Heart

Transgenic and mutant murine models of cardiovascular disease provide a means by which the pathophysiology of cardiovascular disease may be investigated in an intact organism. However, cardiac MR is affected by cardiac and respiratory motion artifacts, exacerbated by the high heart rate (400–600 beats/min), the high respiratory rate (30–60 breaths/min), and the small dimensions of the mouse heart. To reduce motion artifacts in cardiac MR, motion-gating strategies have to be employed to reduce the level of motion artifact using a variety of sensor technologies. Cardiac gating enables synchronization of a MR sequence to the cardiac cycle such that data acquisition occurs from spins from the same region of interest and the same phase within the TR interval, minimizing the influence of cardiac motion. Respiratory motion also needs to be avoided. Artificial ventilation (not ideal due to its invasive nature) or reduction of the motion artifact by sensing methods can be employed.

Cardiac mass estimates using MRI have been shown to be highly accurate, reproducible, and observer- and technician-independent when compared to that obtained at necropsy [58–61]. Increases in left ventricular mass and volume were revealed by MRI in transgenic mice and were evident in mice expressing myocardial tumour necrosis factor compared to littermate controls [62]. MRI has been used for accurate serial assessment of cardiac structure in neonatal, juvenile, and adult mice [63]. As well being used to image heart anatomy, MRI can be used to image the coronary arteries [64]. MRI has also been used to study cardiac malformations of fixed embryos [65].

The use of MRI for morphological (and functional) assessment of the heart is discussed fully in Chapter VI.

(e) Other organs

The ability to distinguish between different soft tissues is one of the main reasons for MRI being at the forefront in the longitudinal *in vivo* monitoring of tissue and organ changes in murine models of disease [48,49,66]. Indeed, as well as determining temporal and regional morphological changes in skeletal muscle, MR techniques have been successfully applied to the study of muscle denervation and reinnervation [67], muscle perfusion [68], muscle fiber-tracking [69] and acute and chronic inflammation [70]. However, studies of skeletal muscle, as well as other organs, are rare in mice arising from the difficulties in scanning such small animals. *In vivo* MRI at 9.4 T, has been used to study schistosoma Mansoni-infection in mouse liver [71], lupus nephritis in a MRL/lpr mouse [71], and liver regeneration in mice following partial hepatectomy [72]. Deoxygenated and oxygenated haemoglobin have different magnetic susceptibilities and this has been exploited to detect high levels of the former in the liver and kidneys of a homozygous alpha-knockout of a transgenic murine model for sickle cell disease, indicating the presence of blood hypoxia in these mice [73]. Furthermore, an enlarged spleen was noted by MRI and consistent with computerized tomography data in a mouse model of AymloidA amyloidosis [74].

Magnetic Resonance Spectroscopy

While MRI provides graphical images of the whole body, organs, and internal structures, MRS can be utilized to obtain metabolic information from different organs *in vivo*. MRS is feasible for any nucleus possessing a magnetic moment and will simultaneously detect compounds containing that nuclei if the compounds are at high enough concentrations, i.e. mM range for ^{1}H MRS. MRS can be used to provide metabolic profiles from ^{1}H-, ^{31}P- and ^{13}C-containing metabolites in the whole body or specific organs. Often for MRS of specific organs, localized MRS is performed, involving surface coils or the use of gradients to define an area or voxel of interest. The localization obtainable from surface coils arises mainly from the fact that the excitation of nuclei induced by the coil occurs only in a limited area adjacent to the surface coil, and decreases with increasing distance from the surface of the coil. The area in which the coil is effective is largely determined by the size of the coil, i.e. the larger the coil, the greater the area in which nuclei can be excited. This type of approach is mainly used for the acquisition of ^{31}P spectra principally from skeletal muscle, where the potential for contamination from other tissue is relatively low.

Localization methods commonly used for ^{1}H MRS are STEAM (STimulated Echo Acquisition Mode) and PRESS (Point RESolved Spectroscopy). PRESS does not allow the creation of multiple quantum coherences in coupled spin systems, however, the signal intensity obtained using PRESS localization methods is double that obtained by STEAM and hence, is the technique of choice for most *in vivo* MRS studies. ISIS (Image Selected *In vivo* Spectroscopy) is commonly used for localization when performing MRS of non-^{1}H nuclei, such as ^{31}P MRS. ISIS is chosen for ^{31}P MRS as the localization technique is relatively insensitive to T_2 relaxation and so, unhampered by the short T_2 relaxation time in ^{31}P MRS.

Spatial localization, not only allows the unambiguous detection of metabolites from a defined volume but also increases the spectral resolution by narrowing resonances (better shimming), exclusion of broad unwanted resonances, and improving water suppression (see below). For further details of the principles and techniques involved in MRS *in vivo*, the reader is referred to de Graff [75].

Localized ^{1}H MR spectra are normally dominated by water which is the major ^{1}H-containing compound ($\sim$40 mM) in cells/tissues. Other ^{1}H-containing metabolites, usually metabolites of intermediary metabolism such as amino acids, lactate, etc., may only be discerned following suppression of the water resonance. Other major components that are observed in the *in vivo* ^{1}H MR spectra of tissues are resonances from lipids especially those arising from the methylene protons of fatty acids chains, leading to concealment of other resonances. Such lipid resonances can be "edited" out of the ^{1}H MR spectrum by using long TE values since the methylene protons have a short T_2 values relative to other protons.

A magnetic nuclei should only give rise to a single resonance in the MR spectrum, however, the magnetic environment of this nuclei can be modified by adjacent magnetic nuclei such that the former gives rise to a multiplet, the complexity of the multiplet depending upon the nature and number of the nearby nuclei. This is termed spin–spin coupling (for a fuller discussion of such interactions, the reader is referred to standard textbooks). Spin–spin coupling can exist between the same nuclei (homonuclear) or different nuclei (heteronuclear). In ^{1}H MRS, despite the production of more complex spectra, coupling of different protons can aid assignment of resonances. However, for other nuclei, such as ^{13}C, although homonuclear coupling is minimal, heteronuclear coupling (to ^{1}H) leads to complex resonances that render the coupled spectra difficult to analyze and also as the area of the one resonance becomes divided between the coupled resonance resulting in a decrease in signal intensity and therefore, visibility of the resonance in the spectrum. While it is preferable to "decouple," i.e. suppress spin–spin coupling, in such situations, decoupling can lead to excessive radio-frequency power deposition, resulting in heating and possible damage of the tissue under study, which is of course of particular concern when investigating live organisms. Thus, decoupling is often not employed unless essential for signal assignment and/or accurate quantification.

The sensitivity of ^{13}C is 1.59%, relative to ^{1}H (100%). The relatively low sensitivity means that natural abundance ^{13}C MRS can only detect compounds that occur at relatively high concentrations *in vivo*, such as mobile lipids and glycogen. However, the low sensitivity of ^{13}C offers the possibility of studying fluxes (of ^{13}C-enriched compounds) through important metabolic pathways due to low or little background interference from endogenous metabolites. Thus, ^{13}C MRS has been used extensively to monitor the metabolism of exogenous ^{13}C-enriched compounds, providing specific and quantitative information about metabolic pathways such as glycolysis, tricarboxylic acid cycle, gluconeogenesis, and pentose phosphate pathway. As an alternative to direct detection of the ^{13}C nuclei, ^{13}C MR spectra can be obtained by indirect (or inverse) detection of these nuclei via bonded ^{1}H, the latter method benefiting from the increased sensitivity of the ^{1}H nuclei.

The sensitivity of ^{31}P (6.63% relative to ^{1}H sensitivity at 100%), is sufficient to enable ^{31}P MRS to be performed *in vivo* and has been used to provide important information regarding tissue bioenergetics, intracellular pH, magnesium concentration, and reaction fluxes.

Apart from providing characteristic metabolic profiles of the whole body or of selected organs, multinuclear MRS can also be used to obtain dynamic biochemical/functional information regarding murine models in terms of phenotyping (see below), e.g. the use of ^{13}C-enriched compounds. This is comparable to conventional organ function tests performed routinely, usually entailing the use of a non-toxic compound that may be metabolized by a specific organ, and the rate of metabolism reflecting the functional state of the organ in question.

MRS can also be performed *in vitro*, comparable to traditional "chemical analysis" using MRS. While MRS *in vivo* can provide much information regarding a living organism, the spectral quality of the data obtained is of an inferior quality to that obtained *in vitro,* rendering assignment and quantification difficult. Thus, *in vitro* MRS of extracts of tissues is often required to aid assignment of MR spectra *in vivo*. *In vitro* MRS data can also be used for phenotyping of murine models and will be discussed briefly later in this chapter.

(a) Adipose tissue

Bodyweights are often used as surrogate measures of adiposity in murine studies of obesity. However, this method is fraught with problems as it assumes a constant ratio between lean and fat mass. More recently, ^{1}H MRS has been developed as a fast and reproducible *in vivo* method to determine adiposity.

^{1}H MRS of the whole body can determine percentage adiposity, comparing favorably with that by chemical analysis of the carcase [76]. Unlocalized ^{1}H MR of the whole body yields a spectrum dominated by one

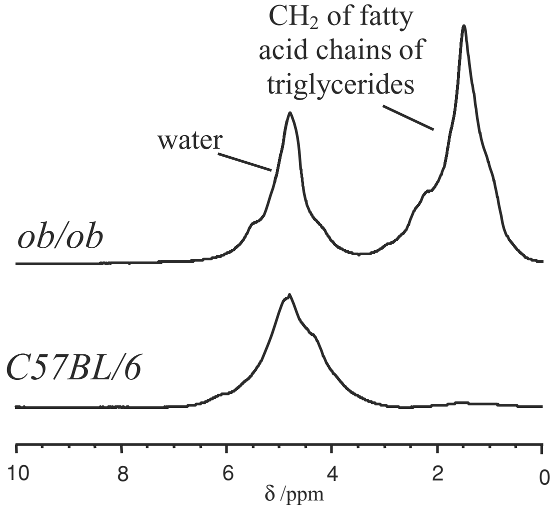

Figure 8. Whole body ^{1}H MRS of a C57BL/6 and an obese *ob*/*ob* mouse.

resonance from water (Figure 8). At lower frequency, another resonance is also discernable but more so, in obese animals. The other resonance arises from the methylene protons of triglycerides, which is the major component of AT. The area under each resonance or integral is proportional to the number of protons giving rise to that particular resonance. Thus, quantification can be performed with spectroscopic processing packages to yield a ratio of the water to lipid peak, from which the percentage adiposity may be calculated using the following equation:

$$\%\,\text{adiposity} = \frac{100 \times I_{(\text{lipid})}}{I_{(\text{lipid})} + I_{(\text{water})} + 0.38 \times I_{(\text{water})}} \qquad (1)$$

where $I_{(\text{lipid})}$ and $I_{(\text{water})}$ are integrals for lipid and water, respectively.

Equation 1 arises from considering that the mass of the whole body arises from the masses of body fat, water, and fat-free tissue. The former two can be estimated by MRS as they are proportional to $I_{(\text{lipid})}$ and $I_{(\text{water})}$, respectively. The fat-free or lean mass has been observed to be related to the total body water by a fixed ratio [77], and confirmed in mice recently by Mystkowski *et al*. [76], to be proportional to 0.38 times that of $I_{(\text{water})}$. We have used ^{1}H MRS of the whole body as a measure of adiposity in a murine model devoid of the corepressor protein RIP140 showing their tendency to leaness [49], inter-strain differences in the handling of dietary omega-3-fatty acids [78] and the effect of voluntary exercise on adiposity in C57BL/6J mice [79]. ^{1}H MRS of the whole body has also been used to show that aromatase-deficient mice have a phenotype of increased adiposity [80].

An alternative MRS method for measuring total adiposity is based on MR relaxometry, which unambigously separates water and fat due to the very different T_1 and/or T_2 relaxation times [81–83]. MR relaxometry was shown to correlate well with body composition obtained by DEXA and chemical analysis, and has been used to detect diet-induced changes in body composition with no change in body weight in mice [82].

Although MRI can also be used to determine total and regional adiposity, in terms of analysis time, MRS provides a more rapid and relatively accurate assessment of adiposity. For MRS, analysis time can be as quick as 10 min compared to up to 4 h for MRI. Thus, MRS would be more suitable for studies in which repeated measures are required or large numbers of experimental animals need to be scanned, while MRI would be more suitable for research where regional as well as total adiposity is needs to be measured.

^{13}C MRS can provide information regarding the type of lipid in the AT deposits in the whole body. The insensitivity of ^{13}C MRS is such that only the carbons of AT are present in high enough concentrations to be detectable by ^{13}C MRS. Thus, ^{13}C MRS of the whole body (Figure 9) allows estimation of the degree of deposition of certain lipid types and can provide an estimate of the proportion of monosaturated fatty acids carbon relative to polyunsaturated fatty acids carbon. For example, we have recently shown increased deposition of polyunsaturated fatty acids in AT of lean (C57BL/6) mice compared to genetically obese (*ob/ob*) mice following dietary supplementation of omega-3 fatty acids [78]. The studies mentioned have used ^{13}C without ^{1}H decoupling. Although decoupling is not essential, it will simplify spectral analysis and aid quantification. ^{13}C MRS of specific depots or the whole body can be used to investigate differences between strains in the handling of dietary lipid types in the whole body and characterization of nutritional fat deficiencies and abnormalities in fatty acid pathways.

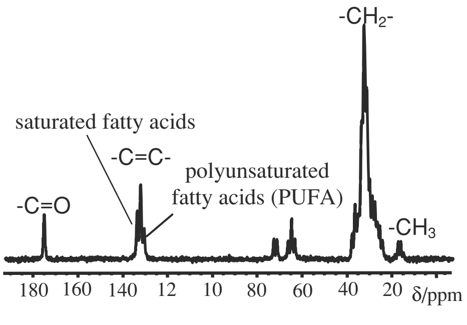

Figure 9. Whole body ^{13}C–^{1}H coupled MRS of an obese *ob*/*ob* mouse.

(b) Heart

^{1}H and ^{31}P MRS has been used to monitor differences in cardiac metabolism between isolated hearts from wild-type and iNOS-overexpressing hearts [84]. Cardiac energetics studied by ^{31}P MRS also differ between murine models lacking different muscle-specific isoenzymes of creatine kinase [85]. A fuller discussion of the use of multinuclear MRS to study cardiac function is detailed in Chapter VI.

(c) Brain

Although localized ^{1}H MRS *in vivo* has been used extensively to study brain metabolism in the rat [86,87], there are relatively few studies involving mouse brain, probably due to its small size and the difficulties in compensation of the local magnetic field inhomogeneities. Most *in vivo* studies involving ^{1}H MRS of mouse brain have concentrated on determining the levels of a limited number of brain metabolites, including N-acetylaspartate (NAA), lactate, creatine (Cr), myo-inositol (mI), or choline. This limitation arises from the relatively long TE values often employed for MRS, usually ~40 ms, shorter values being more difficult to achieve due to the requirement of exceptionally strong gradients to suppress eddy current artifacts. Measurement of NAA levels is often used as in indicator of healthy neuronal function and so, frequently employed to assess neuronal function in different transgenic mice models but may reflect the degree of cellular integration in the central nervous system [88]. NAA levels are decreased in a Huntingdon's disease murine model [89,90] while increased NAA levels were observed in a knockout mouse model for Canavan disease [91]. Levels of NAA were revealed to be similar between the mdx (murine model of Duchenne muscular dystrophy) and control mice, suggesting minor, if any neuronal necrosis in the dystrophic brain [92]. The mI/Cr ratio was significantly increased and the NAA/Cr decreased in the Ts65Dn mouse brain, a murine model of Down syndrome, and comparable to ^{1}H MRS findings in human adults with Down syndrome [93]. Brains of creatine kinase double knockouts mice exhibited 20–30% decrease in levels of total creatine and a similar increase in the level of neuronal NAA, whereas changes in mI and glutamate did appear to be mutation type and brain region specific [36]. Increased guanidinacetate, reduced Cr, and creatinine levels were observed in the brain of mice with guanidinacetete N-methyltransferase deficiency [94]. Transgenic mice expressing mutant human amyloid precursor protein, exhibited increased NAA, glutamate, and taurine in the ^{1}H MRS metabolic profile of the brain *in vivo* [95]. Lactate—the end product of glycolysis—is readily discerned in the ^{1}H MRS spectra of mouse brain and can be used to monitor development of ischemic episodes [96], which may be of particular relevance in determining the susceptibilities of certain strains to cerebral ischemia. Indeed, *in vivo* localized ^{1}H MR cerebral metabolite profiles of different mouse strains, collected before and after 1 h of global irreversible ischemia, showed that the pronounced vulnerability of C57BL/6 mice to brain ischemia is linked to strain-dependent differences in cerebral energy metabolism [97].

Full quantitative assessments of cerebral metabolites in mouse strains *in vivo* are rare, due to difficulties in resolving resonances arising from local magnetic field inhomogeneities [36,97–99]. However, the development of a second-order shim system strong enough to compensate for non-linear field inhomogeneities in the selected volume of interest, as well as more efficient methods of localization and water suppression, has enabled high quality spectra to be obtained from the murine brain (Figure 10, [99]). This coupled with the use of much shorter TE value (2 ms) allowed for the reliable quantification of over 16 brain metabolites from 5 to 10 μl volumes of mouse brain *in vivo*. The highly resolved ^{1}H MR metabolic profiles, obtained from different regions of the brain, as well as in different strains, provide qualitative and quantitative information on inter-species variations as well as inter-regional variation within strain [99]. Thus, ^{1}H MR metabolic profiling of the brain (and possibly other tissues) will become a powerful tool in the arsenal available to researchers trying to elucidate genotype–phenotype correlates.

A number of studies have reported the use of ^{13}C MRS to investigate brain metabolism, principally in the rat brain. ^{13}C MRS of the brain has been used to measure fluxes associated with cerebral glucose and glutamate metabolism, providing quantitative information on metabolic fluxes *in vivo*. [1-^{13}C]-glucose has been used extensively in ^{13}C MRS, principally due to its cheapness but also, that the transfer of the ^{13}C label to [4-^{13}C]-glutamate is indicative of the most active energy-producing metabolic pathways, glycolysis, and the neuronal TCA cycle [100]. The investigations can be refined by the use of [1,6-^{13}C]-glucose which exhibits nearly identical patterns of labeling, which although more expensive, has double the sensitivity of [1-^{13}C]-glucose due to the enrichment of two pyruvate molecules for one of [1,6-^{13}C]-glucose. [2-^{13}C]-glucose has been used as a direct indicator of analpherotic activity by the accumulation of astroglial [3-^{13}C]-glutamine. Using this methodology, Sibson *et al.* [101], observed differences in analpherotic activity in the rat brain exposed to different concentrations of blood ammonia. [2-^{13}C]-acetate has also been used to distinguish between neuronal and astroglial metabolism, since it is almost exclusively metabolized in astroglial cells. ^{13}C MRS labeling experiments have led to the establishment of a basic mathematical model of brain energy metabolism and (glutamatergic) neurotransmission, verified in rat and human brain [102,103]. The use of ^{13}C MRS in the study of brain biochemistry and function is reviewed in detail by de Graaf [75]; Zwingmann and Liebfritz [99]; Gruetter *et al.* [104]. Such methodology

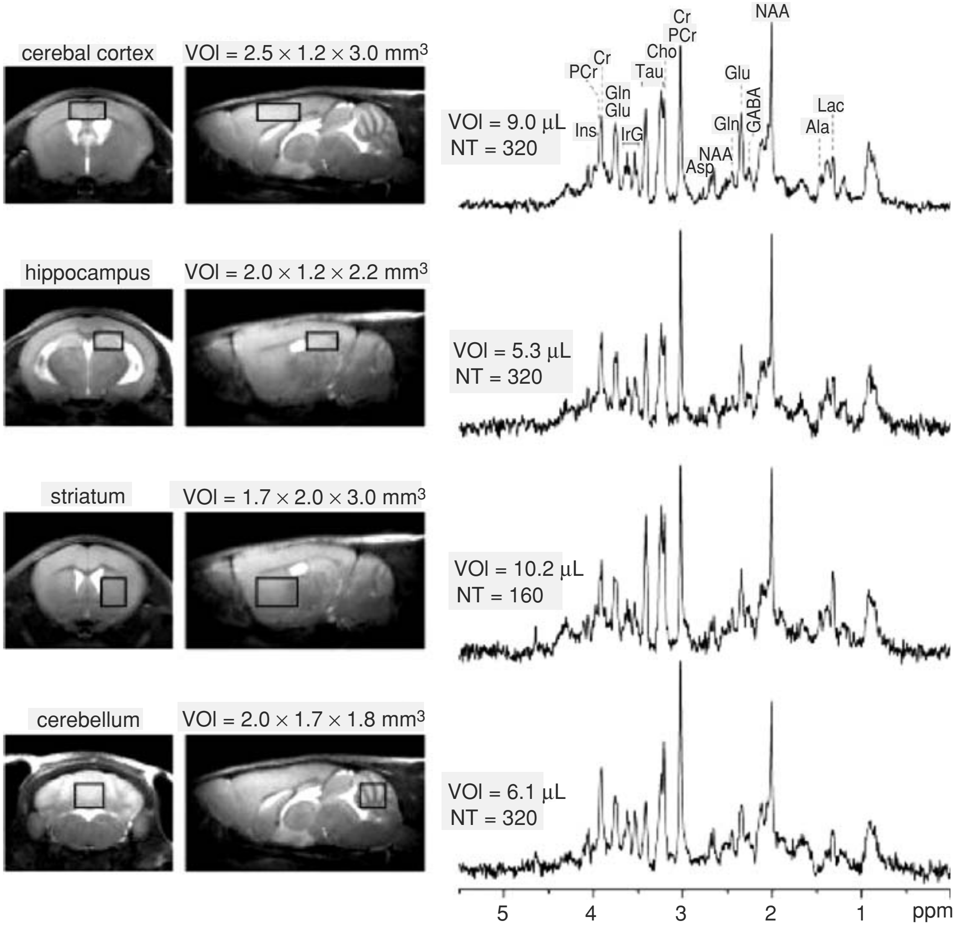

Figure 10. Multislice RARE images of the mouse brain (C57BL/6) with the volumes of interest (VOIs) centered in cerebral cortex, hippocampus, striatum, and cerebellum, and *in vivo* ^{1}H NMR spectra measured from the corresponding brain regions. RARE MRI: in-plane resolution 80 μm × 80 μm, slice thickness 1 mm, TR/TE = 4000/60 ms. Localization sequence: STEAM, TE = 2 ms, TR = 5 s, number of averages = 160–320, VOI = 5 − 10 μl. Processing: Gaussian multiplication $\{f(t) = \exp(-(t - t_{\max})^2/2\sigma^2)$, $t_{\max} = 0.05$ s, $\sigma = 0.085$ s$\}$, Fourier transform, zero-order phase correction. No water signal removal or baseline corrections were applied. (Reproduced with permission [99].)

can also be applied to murine models with the use of adapted coils and sequences, as with ^{1}H MRS of the brain (see above). Indeed, *in vivo* ^{13}C MRS has been used to characterize cerebral glucose metabolism in a transgenic animal model of amyotrophic lateral sclerosis, a neurodegenerative disorder [105].

^{31}P MRS can be employed to monitor brain energetics and was used to study the brains of creatine kinase double knockout mice, revealing normal levels of ATP and inorganic phosphate, as well as pH, although phosphocreatine levels were almost completely undetectable [36]. High levels of guanidinoacetate phosphate and reduced phosphcreatine levels were observed in a knockout mouse model of guanidinoaceate N-methyltransferase deficiency [94]. Neural energetics in a mouse expressing human myoglobin showed no significant difference from wildtype mice [106].

(d) Muscle

^{1}H MRS has been recently used to determine triglyceride deposition in skeletal muscle and liver in animal models [107–112]. The main objective of this work has been to investigate the relationship between intramyocellular lipids (IMCLs) and insulin resistance. The feasibility of this technique has been demonstrated in rats and mice and levels of IMCL appear to be affected by several factors including age, gender, diet and exercise, muscle fiber-type, as well as the genetic background of the animals. For example, healthy young rats have been shown to have higher levels of IMCL compared to older rats and obese rats showed significantly higher IMCL levels than controls. Despite this variability, a number of studies have shown that IMCL levels are correlated positively with measures of obesity and negatively with insulin sensitivity. Moreover, levels of IMCL have been shown to be pliable to manipulation by nutritional and pharmacological interventions, with concomitant changes in insulin sensitivity. Thus, *in vivo* ^{1}H MRS is presently being used as a non-invasive method to determine the efficacy of emerging therapy in the treatment of obesity and insulin resistance.

Multinuclear MRS (^{31}P and ^{13}C) has been pivotal in unraveling the mechanisms associated with muscle metabolism in murine models of disease. ^{31}P MRS has been extensively utilized to study the metabolic and non-metabolic factors associated with muscle fatigue. The results are consistent with the fact that elevated levels of inorganic phosphate, P(i), can cause a substantial proportion of the loss in muscular force and power output during fatigue; but later fatigue may arise from impaired activation beyond the neuromuscular junction [113–117]. While in sepsis there is an overall decrease in energy availability, which is worsened by PCr depletion [118].

The ability of ^{31}P MRS to detect phosphorylated compounds has also been successfully used to measure the muscle glucose-6-phosphate (G6P) concentration after exercise and in non-insulin-dependent diabetes mellitus. Time course studies have emphasized the importance of G6P concentration as an intracellular regulatory effector of glycogen synthesis rate *in vivo*. The authors went on to show that the majority of the flux control of muscle glycogen synthesis is at the glucose transport/hexokinase step—a step that in turn may be compromized in insulin resistance [119–122]. Thus, ^{31}P MRS can be used to assess muscle function in different transgenic murine models. For example, in a murine model of guanidinoacetate N-methyltransferase deficiency, the first discovered creatine deficiency syndrome, elevated levels of guanidinoacetate phosphate, and reduced levels of creatine phosphate were observed by ^{31}P MRS of SM in these transgenic mice [94]. In another ^{31}P MRS study of muscle [123], these mice were found to be able to cope with mild ischemic stress, despite the lack of phosphocreatine, by using guanidinoacetate phosphate for high-energy phosphoryl transfer.

(e) Liver

Multinuclear MRS has also been applied to the study of liver physiology and metabolism [124]. ^{1}H MRS of the liver has been proposed as an alternative and non-invasive method for determining liver lipid levels in rodents [108,112]. Localized *in vivo* ^{1}H MRS of the liver yields a spectrum consisting of peaks from water and the methylene protons of the fatty acid chains of intrahepatocellular lipid (Figure 11). Traditionally, methods of quantifying liver fat are by biopsy, which is non-ideal for longitudinal and/or interventional studies. Garbow *et al.* [108] observed an excellent correlation between *in vivo* MRS and *ex vivo* chemical analysis determinations of liver lipids. ^{1}H MRS of the liver provides a method of measuring the extent of intrahepatocellular lipid deposition between different strains of mice (Figure 11). Thus, *in vivo* MRS of the liver is an extremely valuable technique in longitudinal studies for monitoring changes in lipid levels.

As previously mentioned, the low sensitivity of ^{13}C MRS renders it a suitable nucleus for tracer experiments to measure metabolic fluxes. The use of ^{13}C-labeled compounds as tracers has enabled many metabolic pathways in the liver to be investigated [124]. The role of fructose-2,6-bisphosphate (FBP) in regulation of glucose fluxes was assessed using *in vivo* ^{13}C MRS in a mouse with elevated levels of FBP, showing that elevated FBP levels result in increased hepatic glycogen storage through indirect synthesis of glycogen [125]. The liver is readily amenable to perfusion *ex vivo* and studies have been performed on isolated murine livers to determine metabolism of exogenously administered compounds in the perfusion medium using ^{13}C MRS to determine best methods of liver preservation for transplantation [126]. Currently, relatively few studies have used such methodology to investigate differences in metabolic fluxes between transgenic animals.

Similarly, ^{31}P MRS has been extensively used to study cellular bioenergetics (see above) in rats and man but there are few studies of its use in the mouse liver. These studies have concentrated in monitoring hepatic energetics in transgenic mice expressing different forms of isoenzymes of creatine kinase in the liver [127–130], creatine kinase is normally absent in the liver. Such studies have shown that the presence of creatine kinase in the liver does not affect free ADP levels [127]. No depletion of hepatic ATP was observed in transgenic mice expressing creatine kinase in the liver given a fructose challenge [128]. The phosphocreatine produced in the livers of creatine kinase expressing mice protected these mice from hypoxia and ischemia as evident by ^{31}P MRS [129].

(f) Metabolic profiling of biofluids

Metabolic MR profiles can be obtained from biofluids or extracts of organs, and such profiles are often

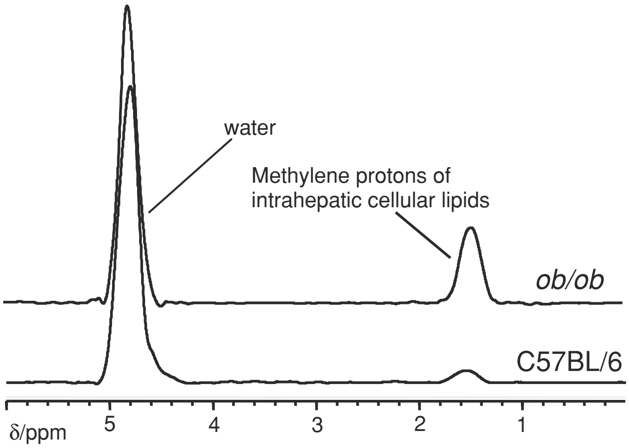

Figure 11. Localized *in vivo* ^{1}H MR (PRESS) spectrum from a 3 mm × 3 mm × 3 mm voxel located in the liver of a C57BL/6 and an obese *ob/ob* mouse.

characteristic for the type of biofluid or extract. Changes in metabolism are observable in MR spectral profiles of biofluids or tissues and this data are reflective of the metabolic status of an organism, and has therefore been used to investigate pathophysiological and toxicological processes (reviewed by Lindon *et al.* [131]). Due to the complexity of the spectral data, multivariate statistical methods are commonly employed to enhance interpretation. Such techniques can be extended to phenotyping such that changes in metabolism between different strains and effects of inter-species differences resulting from interventional treatment can be discerned in the metabolic profile of biofluids and extracts of tissue [132–134]. However, caution must be employed for phenotyping studies since metabolic profiles can be affected by a number of physiological factors. Factors include dietary variation [133], exercise and physical activity [135], normally regulated diurnal cycles [136], oestrus or menstrual cycle-related processes [136], and genetic drift [133]. To address this issue with respect to diurnal variation, pre-filtering of the data by orthogonal signal correction was applied, resulting in removal of the variations arising from diurnal variation, and hence, more accurate interpretation of the data [137]. For a fuller discussion of the use of metabolic profiles (especially obtained by ^{1}H MRS) for functional genomic research, the reader is refered to Griffin [138] and Griffin *et al.* [139].

Conclusions

The advent of high-field MR systems is making a reality the routine application of MRI/MRS techniques to the study of murine models of disease. *In vivo* imaging techniques—including MRI—are likely to play a pivotal role in elucidating the function of many candidate genes in pre-clinical investigations and therapy development.

Introduction

Magnetic resonance imaging (MRI) is a technique allowing non-invasive *in vivo* imaging with excellent discrimination between different types of soft tissue. The contrast in a standard MR image depends both upon variations in tissue water density and the physicochemical environment of the water. For this reason, it is not only possible to differentiate tissue types [e.g. gray matter, white matter, and cerebrospinal fluid (CSF) in the brain] but also normal and abnormal physiological states (e.g. to identify regions of cerebral edema following a stroke). More recently, methods have been developed, which allow more dynamic assessment of changing physiological parameters, either through their effect on MR relaxation parameters or via some other modulation of the MR signal. In this chapter, the most common MR methods used for imaging the brain will be described, and the mechanisms responsible for the sensitivity of these methods to pathophysiology in brain disease will be explained.

Image Contrast and Intrinsic MR Parameters

The physical and chemical environment of the water molecules in the brain affects the MR signal intensity by altering the transverse and longitudinal MR relaxation rates. This allows the visualization of biophysical processes that occur on a spatial scale many times smaller than the nominal image resolution. MR sequences can be designed to have their image contrast dominated (or "weighted") by one or other of the relaxation times, and by so doing sensitize them to the factors influencing that particular parameter.

T_1-weighted Imaging

T_1 (the longitudinal or spin-lattice relaxation time) is the time constant for the exponential recovery of the longitudinal magnetization. The exact details of the relaxation mechanisms are complex, but they are facilitated by the presence of microstructures such as macromolecules and cell membranes (known as the lattice) that can absorb the energy of the excited protons via dipolar interactions. This energy transfer is most efficient when the rotational frequency of the molecules is in the same range as the Larmor frequency (i.e. in the 50–400 MHz range for typical MR scanner field strengths). In practice, this means that T_1 becomes shorter as the molecular mobility decreases, but increases again for very slow molecular motion, such as in solids. In biological systems, tissue environments that contain abundant microstructural elements are characterized by shorter T_1 relaxation times, and regions where structure is less restricted or has broken down (e.g. in CSF or areas of edema; Figure 1) T_1 is longer. Also, since the efficiency of T_1 relaxation depends on the proportion of molecular rotations at the Larmor frequency, T_1 values vary (typically increase) with magnetic field strength.

In order to achieve T_1 weighting in MR images, one of the two main approaches are generally taken. The amount of signal recovery during the recovery time (TR) of a standard spin echo (SE) or gradient echo (GE) sequence is determined by T_1, and so selecting a TR value that allows almost full relaxation for tissue with short T_1 and minimal relaxation for tissue with long T_1 generates strong T_1 contrast. As an alternative to this saturation recovery method, the inversion recovery (IR) method can be used, either to selectively null the signal from certain tissue types (e.g. FLAIR to eliminate CSF signal [1]) or to generate the desired T_1 contrast. If a set of images

(a) T_1 map (b) T_2 map (c) ADC map

Fig. 1. MR parameter maps of a coronal slice of the rat brain 24 h after a 30 min occlusion of the middle cerebral artery (supplying the territory on the left side of the images). Hyperintensity in the T_1 and T_2 maps indicates the progression of vasogenic edema; low ADC values indicate increased restriction of water diffusion caused by cell swelling (cytotoxic edema).

is acquired with a range of recovery or inversion times, T_1 maps can be calculated by fitting the image data to theoretical T_1-dependent signal curves. Compared to images which are merely T_1-*weighted*, T_1 maps provide a more specific quantitative assessment of MR signal changes, since the influence of all other factors affecting image contrast (e.g. T_2, diffusion, etc.) is removed.

T_2-weighted Imaging

T_2 (the transverse or spin–spin relaxation time) is the time constant for the decay of the transverse magnetization. The main mechanism for transverse relaxation relies on intermolecular magnetic interactions between the hydrogen nuclei of a water molecule and the protons of neighboring molecules. The random Brownian motion of water molecules means that these interactions are irreversible and therefore not undone by a 180° refocusing pulse. This interaction becomes more efficient when the contact time between molecules is relatively long, e.g. in viscous media. When the rotational correlation time of the molecules is short, such as for free water molecules, the spin–spin interactions will be brief and so T_2 is relatively long ($\sim$3 s). Water molecules interacting with macromolecules or solid surfaces generally have slower tumbling rates, leading to a reduction in the relaxation time. Because water mobility often varies substantially between tissue types, and changes in situations of cellular stress, T_2-dependent contrast is commonly used in MRI studies to depict pathology (Figure 1).

T_2-weighted imaging is performed using SE sequences with long TR and echo times (TEs) chosen to maximize the difference in signal intensity between the tissues of interest. The use of an SE sequence ensures that dephasing of the transverse magnetization caused by static field inhomogeneities is refocused, and signal loss is determined by processes that are dynamic on the timescale of the TE. In addition to the dipolar spin–spin interactions described above, this can include the effects of diffusion through intrinsic magnetic field gradients (such as those surrounding venous blood vessels) and magnetization transfer (see below). As with T_1 imaging, quantitative T_2 maps can be calculated by acquiring images over a range of TEs.

T_2^*-weighted Imaging

If a 180° pulse is not used to refocus the transverse magnetization, the signal decay is dependent on "static" field inhomogeneities as well as the factors described above for T_2 relaxation (in this context, "static" refers to effects which do not change over the time frame of the signal acquisition period, which is typically in the range 10–100 ms). The presence of small local magnetic field variations results in a range of Larmor spin precession frequencies and thus in a loss of phase coherence, causing a faster decay of the transverse magnetization. This apparent transverse relaxation rate without RF refocusing is described by the time constant T_2^*. The sensitivity to field disturbances can be exploited as a source of contrast in tissue, since such magnetic field inhomogeneities typically occur at interfaces of structures with differing magnetic susceptibilities, such as soft tissue and bone or tissue and blood. The main applications of T_2^*-weighted imaging in animal models of disease are blood oxygenation level-dependent (BOLD) imaging and contrast agent enhanced imaging. These methods are described in detail below.

T_2^*-weighted imaging is performed using GE sequences with TEs chosen to maximize sensitivity to the tissue changes of interest. However, it is important to note that the increased sensitivity to field disturbances can also cause problems in regions of the brain where gross magnetic field inhomogeneity exists. Imaging of such regions may be precluded since they will exhibit short T_2^* values, leading to gross signal dropout at the TEs required to generate significant T_2^* weighting in other parts of the brain. In order to reduce this problem, "z-shimming" techniques may be used [2,3], at the expense of compromised signal-to-noise ratio (SNR) values in the other areas of the brain. GE sequences can use short TR, which reduces the imaging time but also introduces T_1 weighting to the signal intensity.

$T_{1\rho}$-weighted Imaging

If a continuous RF pulse with amplitude B_1 is applied immediately after spin excitation, the transverse magnetization becomes "spin-locked" to this applied B_1 field. An energy level system is set up in the transverse plane and the rate at which the excited magnetization returns to equilibrium is known as $T_{1\rho}$ (or "T_1 in the rotating frame"). The importance of $T_{1\rho}$ imaging is that, in the same way that T_1 relaxation is sensitive to molecular motion at frequencies determined by the main magnetic field ($\omega_0 = \gamma B_0 = 42.577 \times 10^6 \times B_0$, i.e. the MHz range), $T_{1\rho}$ relaxation is sensitive to molecular motion at frequencies determined by the B_1 field ($\omega_1 = \gamma B_1$ where $B_1 \sim 1$ mT, i.e. ω_1 is in the kHz range). This means that $T_{1\rho}$ contrast is sensitive to the relatively slow motion characterizing the macromolecular components of biological systems, and so can offer an alternative contrast regime compared to T_1- and T_2-weighted imaging. The use of $T_{1\rho}$ imaging for *in vivo* studies is still at an early stage of development. However, it has recently been shown that $T_{1\rho}$ can provide more specific prognostic information than other MR parameters regarding tissue state following transient ischemia [4]. $T_{1\rho}$ imaging has also been used to investigate, *inter alia*, brain tumors [5] and articular cartilage [6]. $T_{1\rho}$-weighted imaging is usually performed using a magnetization preparation scheme followed by a rapid imaging sequence. For example, a $90_x°$ excitation pulse followed by the continuous wave RF spin locking pulse for a given period; a subsequent $90_{-x}°$ flip-back pulse will produce longitudinal magnetization with amplitude related to $T_{1\rho}$. Echo planar or FLASH imaging can then be used to produce a $T_{1\rho}$-weighted image.

Taking Advantage of MR Sensitivity to Dynamic Physiological Processes

BOLD Imaging

BOLD imaging relies on the fact that the deoxyhemoglobin molecule is paramagnetic and so has a different magnetic susceptibility than other brain tissue. As a result, blood vessels containing deoxyhemoglobin are surrounded by small magnetic field gradients, which decrease the T_2^* value of the surrounding tissue and consequently reduce the signal intensity in a T_2^*-weighted image [7,8]. The degree to which signal intensity is reduced depends on the absolute amount of deoxyhemoglobin in nearby blood vessels, and BOLD imaging is primarily concerned with localized changes in signal intensity which reflect changes in local deoxyhemoglobin levels and, by implication, changes in blood flow and/or neuronal activity.

Under normal conditions, cerebral blood flow (CBF) is autoregulated in the brain within a well-defined range. However, in certain circumstances, CBF can be temporarily adjusted in response to a stimulus. For example, during periods of hypercapnia (inhalation of abnormally high levels of CO_2), the cerebrovascular response acts to increase CBF. Since the oxygenation level of arterial blood is normal (close to 100%) and oxygen metabolism in the brain does not change during hypercapnia, this effectively means that an excess of oxygenated blood is delivered to the brain, and consequently the venous blood is more oxygenated than normal i.e. the amount of deoxyhemoglobin in the veins is lower than normal. This causes an increase in T_2^* of the tissue surrounding the veins, or equivalently an increase of signal intensity in a T_2^*-weighted image. Figure 2 shows an example of a T_2^*-weighted imaging image intensity time course during hypercapnia in the rat brain.

Transient alterations in CBF also occur when the brain is functionally activated. This effect is the basis of

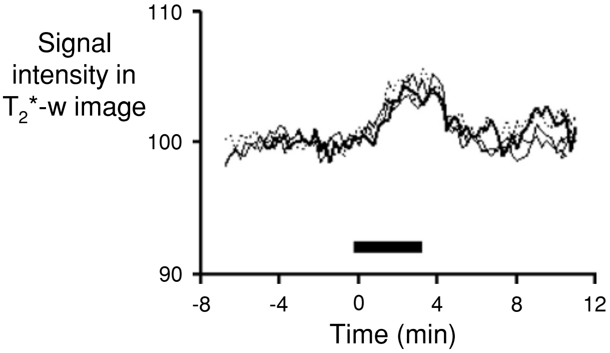

Fig. 2. Time course data from a region of gray matter in the rat brain. At time = 0, hypercapnia was initiated by the addition of 15% CO_2 to the inspired gases (800:400 ml/min N_2O:O_2 with 0.8% halothane anesthesia) and maintained for 3 min. During hypercapnia cerebral blood flow increases, causing a washout of deoxyhemoglobin from the venous vessels of the cerebral vasculature, and thus an increase in signal intensity in a T_2^*-weighted image.

functional MRI (fMRI). In this case, an increase in neuronal activity causes local CBF to increase by an amount which is greater than that needed to satisfy the elevated metabolic demand. As with hypercapnia, the result is a decrease in the amount of venous deoxyhemoglobin and an increase in signal intensity in a T_2^*-weighted image. It is therefore possible to correlate localized functional activation in the brain to experimentally controlled cognitive stimuli. The maximum possible spatial resolution of this method is likely to be limited by the proximity of the activated tissue to its venous vasculature. It should be noted that the BOLD effect is also observed in T_2-weighted imaging, due to dynamic dephasing effects. At high magnetic field strength, T_2 BOLD contrast is heavily weighted toward the capillary compartment of the vasculature and so is more likely to be spatially representative of the region of neuronal activation than T_2^* BOLD, which is dominated by larger venous effects [9]. For a full review of fMRI, the reader is referred to the many texts dedicated to this topic [10–12].

Angiography

Magnetic resonance angiography (MRA), a method used routinely in clinical radiology for imaging large vessel blood flow [13], has recently been adapted for the visualization of cerebral vasculature and bulk blood flow in small animals. Studies have typically employed the 3D time-of-flight (TOF) method [14]. A 3D GE sequence with relatively short TR, short TE, and moderate flip angle is employed. During the image acquisition, the volume of interest experiences multiple RF pulses and therefore the longitudinal magnetization of stationary spins becomes partially saturated and these tissues appear dark in the image. Blood flowing into the image volume during the acquisition is initially fully magnetized and therefore appears hyperintense relative to non-moving tissue. The sequence yields a stack of images, which may be processed using a maximum intensity projection (MIP) algorithm to generate pseudo-3D displays of the vascular anatomy (Figure 3).

Since inflowing blood becomes progressively more saturated while it remains within the imaging volume, by judicious choice of TR and flip angle it is possible to maximize contrast for particular flow velocities: parameters are commonly chosen to maximize the conspicuity of arteries relative to that of veins. In order to avoid signal loss due to velocity-induced spin dephasing, flow-compensated imaging sequences are commonly employed. The choice of the shortest possible TE and the highest available spatial resolution (i.e. the smallest voxel size) is also helpful in this respect. Each repetition of the imaging sequence may be preceded by an off-resonance saturation pulse designed either to further suppress stationary background tissue signal by exploiting the magnetization transfer effect (see “Magnetization Transfer Imaging” section below), or to selectively suppress signals from short T_1 fatty tissues which may otherwise produce confusing artifacts. Vessel conspicuity may be further improved by the use of T_1-shortening blood-pool contrast agents [15].

Applications of 3D TOF–MRA in animal models of disease have included visualization of the effects of vessel occlusion and reperfusion in models of cerebral ischemia in rats [16–18] and mice [19], identification of strain-dependent variations in cerebrovascular anatomy [20], and to identify cerebrovascular abnormalities in a transgenic mouse model of Alzheimer’s disease [21].

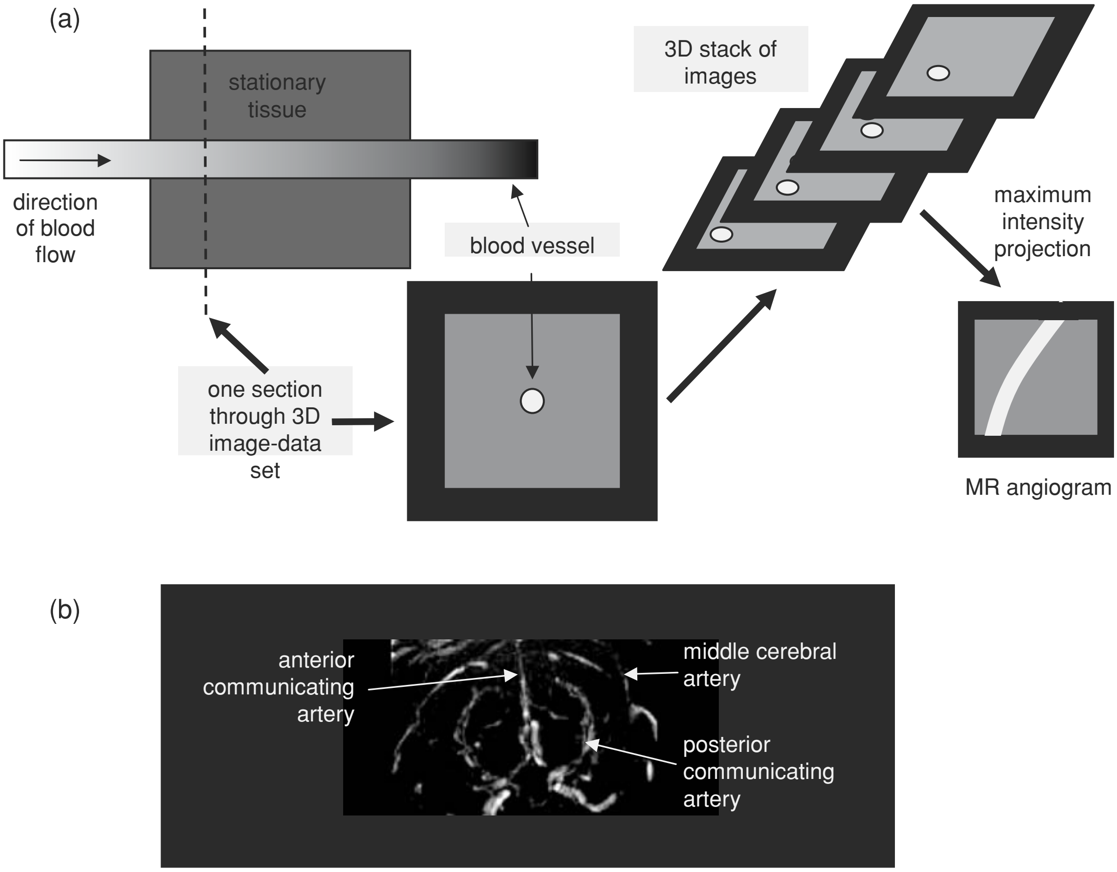
Using Exogenous Contrast Agents to Enhance Image Contrast

In addition to the various physiological sensitivities available based on the intrinsic MR parameters of brain tissue, further contrast manipulation is possible with the introduction of exogenous contrast agents. These techniques, described in more detail in other chapters in this book, are covered briefly here for completeness.

T_1-weighted Dynamic Contrast Enhanced MRI

In the normal brain, the integrity of the blood–brain barrier (BBB) means that it is impermeable to low-molecular weight contrast agents such as Gd-DTPA [22]. These contrast agents therefore remain intravascular and, while causing a transient decrease in T_2 and T_2^* during the passage of the bolus through the cerebral vasculature (see “Perfusion Imaging” section below), have no effect on the T_1 relaxation of extravascular brain tissue. This exemplifies one of the crucial differences in the mechanisms which enhance transverse and longitudinal relaxation: the creation of microscopic magnetic field gradients around vessels containing paramagnetic or superparamagnetic [such as ultra-small superparamagnetic iron oxide (USPIO)] particles causes extravascular T_2 and T_2^* values to decrease, whereas the requirement for direct interaction between the contrast agent and the water molecules leaves extravascular T_1 unaffected. However, disruption of the BBB in many disease states leads to the leakage and accumulation of contrast agent media into the affected tissue. In this situation, T_1 values are reduced and the signal intensity in a T_1-weighted image increases.

In order to maximize the attainable information from a T_1-weighted contrast enhanced study, a time course of T_1 images is acquired. This time course covers a baseline period, followed by the intravenous injection of a small volume of contrast agent and the subsequent collection of



(a)
stationary tissue
direction of blood flow
blood vessel
one section through 3D image-data set

maximum intensity projection
MR angiogram
(b)
anterior communicating artery
middle cerebral artery
posterior communicating artery

Fig. 3. (a) Schematic diagram showing the principles of time-of-flight (TOF) MR angiography. Blood flowing into the imaging volume at left is fully magnetized and therefore appears bright in contrast to the magnetically saturated stationary tissue. Note blood becomes increasingly saturated during its residency in the imaging volume, and thus contrast is typically higher for fast-flowing arterial blood relative to that of venous blood. The 3D data set is processed using the maximum intensity projection (MIP) algorithm to yield the final MR angiogram. (b) Axial view MIP reconstruction of a 3D-TOF MR angiogram showing the major cerebral arteries in a rat. (The image orientation is similar to that of the images in Figure 1.)

images during the period of uptake of the contrast agent. It has been demonstrated that the kinetics of the contrast agent uptake can be used to obtain quantitative parameters relating to the integrity of the BBB, and that these parameters improve the clinical utility of the technique compared to merely assessing a single post-contrast image (e.g. in the delineation of tumor margins [23,24]). Kinetic modeling of contrast agent uptake can provide information concerning the BBB transfer and rate constants, the size of the extravascular extracellular volume, the permeability-surface area product of the capillary wall per unit volume of tissue, and capillary blood flow per unit volume of tissue. For more details on the theoretical modeling and methodology of this technique, see Ref. [25].

The main area of application for contrast enhanced T_1-weighted imaging is the study of tumors, where the BBB becomes severely disrupted. Other pathologies in which breakdown of the BBB occurs include inflammation (e.g. in the initial stages of lesion formation in multiple sclerosis [26]), ischemia and ischemia–reperfusion [27], and traumatic brain injury [28].

Mapping Changes in CBV using Blood-pool Contrast Agents

An alternative method to BOLD contrast for mapping cerebral hemodynamic changes in animal models is provided by the use of exogenous intravascular contrast agents such as USPIO colloids. These contain carbohydrate coated iron oxide particles, which are many times larger than gadolinium complexes such as Gd-DTPA and exhibit long half-lives in the blood pool (more than 2–3 h in the rat). The very high magnetic susceptibility of these particles creates significant local field inhomogeneities causing rapid proton dephasing and thus significantly reducing T_2^* (as well as T_2 and T_1) in the surrounding tissue. An increase in cerebral blood volume (CBV) on functional activation increases the tissue concentration of the contrast agent causing a dramatic local decrease in T_2^* and T_2. The magnetic susceptibility of these contrast agents is far greater than that of deoxyhemoglobin leading to a larger signal change, and hence a contrast-to-noise ratio typically 2–6 times (depending upon field strength and the contrast agent concentration) that obtained with BOLD contrast [29–31]. The magnetic susceptibility of the blood is dominated by the presence of the USPIOs and therefore remains essentially independent of deoxyhemoglobin concentration. This yields a measure of relative CBV (rel. CBV) which is not contaminated by changes in blood oxygen saturation. A further advantage of USPIO contrast agents is that their magnetic susceptibility is sufficiently high that the T_2^* in blood itself becomes very short (□10 ms). As a result, the intravascular signal is negligible and signal changes are dominated by hemodynamic perturbations in the capillary bed, and measurements are not confounded by contributions from larger vessels.

CBV mapping using USPIO contrast agents has found application in the study of pharmacologically induced cerebral activation in the rat (e.g. [32]), as well as in specific disease models such as the murine model of Alzheimer's disease [33], the study of functional reorganization after stroke in the rat brain [34] and the investigation of hemodynamic changes in neonatal hypoxic–ischemic encephalopathy in the rabbit [35].

Smart Contrast Agents

Over recent years, the role of contrast agents in *in vivo* MRI has been transformed by the introduction of smart contrast agents. These are biochemically activated agents that are capable of reporting on the anatomical and physiological function of cellular processes. They are described in detail in Chapter 8.

Manipulating the MR Signal to Measure Physiological Parameters

Diffusion-weighted Imaging

All molecules in a fluid are subject to diffusion (Brownian motion), and the extent of this motion depends on the temperature and viscosity of the fluid. Diffusion can be characterized by a diffusion coefficient D, which describes the average root mean square displacement (x) of a molecule as a function of time (t):

$$x = \sqrt{2dDt}, \tag{1}$$

where d is the number of dimensions in which diffusion can occur (usually three for biological systems). In general, the displacement distribution of the molecules is Gaussian, where the mean displacement distance increases with increasing displacement time. However, if the molecules encounter obstacles or barriers to diffusion (e.g. cell membranes), these will affect the nature of the diffusion and potentially limit the maximum displacement. Boundary restrictions imply that the displacement distribution is no longer Gaussian and depends on diffusion time. As a result, the measured diffusion coefficient is referred to as the apparent diffusion coefficient (ADC) and is smaller than the intrinsic D. The value of the ADC is sensitive to the number of barriers, their geometry and their permeability, i.e. to the tissue microstructure, which can change with physiological state. For example, cerebral ischemia causes acute cell swelling (cytotoxic edema) which reduces the diffusivity of extracellular water and is associated with a decrease in the overall tissue ADC (Figure 1c), although the exact mechanism for the ADC change is currently unknown [36].

An MR image is sensitized to diffusion by the application of additional magnetic field gradients (see Figure 4). If a linear field gradient is applied to an ensemble of magnetic spins that have been excited into the transverse plane, the rate of precession depends on the spin's position in the gradient. If an equal and opposite magnetic field gradient is applied soon after the first gradient (i.e. equal amplitude but opposite direction), the spins will precess in the opposite direction by the same amount, and therefore accrue no net phase change. However, if the spin changes its position (by diffusion) in the time between the application of the first and second gradients, the dephasing and rephasing effects of the diffusion gradients will not match exactly and a residual phase shift will remain. Since diffusion is a pseudo-random process, diffusion is equally likely to occur both ways along any given direction, and by variable distances over a large ensemble of spins. This results in a large range of residual phase shifts, with consequential destructive signal interference and loss of overall image intensity. Tissue regions with higher ADCs will exhibit a greater range of phase shifts and thus greater signal loss. The amount of signal loss is also determined by the parameters of the MRI sequence: the amplitude, duration, and time separation between the diffusion-weighting gradients. These are summarized by the so-called b value of

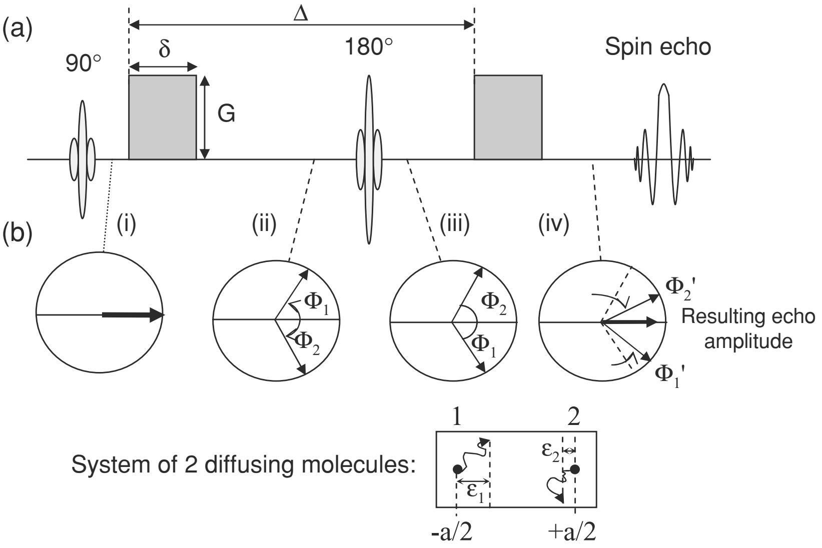

Fig. 4. Schematic representation of the Stejskal–Tanner pulsed gradient experiment and its effect on diffusing molecules. (a) The pulse sequence, with its timing and gradient variables. (b) The state of the transverse magnetization at four stages during the diffusion experiment (i–iv) for diffusing spins, in the case of a simple two spin system which begin with position $z = \{-a/2,\ a/2\}$ and diffuse to $z = \{-a/2 + \varepsilon_1, a/2 + \varepsilon_2\}$ (as shown at the bottom of figure). The transverse magnetization before (i, iii) and after (ii, iv) each of the two diffusion gradient pulses is represented. $\Phi_{1,2}$ represents the phase shift caused by the application of the diffusion gradients. For clarity, T_2 relaxation is ignored. The signal amplitude depends on the phase coherence remaining between the two spins at the time of echo formation. For stationary spins, $\Phi_1 = \Phi_1'$ and $\Phi_2 = \Phi_2'$ so that the application of diffusion-weighting gradients has no effect on the echo amplitude.

the sequence:

$$b_i = \gamma^2 G_i^2(\delta^2[\Delta - \delta/3]), \tag{2}$$

where γ is the gyromagnetic ratio, G_i is the amplitude of the diffusion gradients along direction i, δ is the duration of each of the diffusion gradients, and Δ is the time between the beginning of the first and second diffusion gradients (Figure 4). The reason for adopting this apparently complicated relationship between the b factor and the sequence parameters is so that the image signal loss in a diffusion-weighted image can be expressed as a simple monoexponential decay:

$$S_i = S_0\exp(-\,b_i \cdot \mathrm{ADC}_i), \tag{3}$$

where S_i is the diffusion-weighted signal intensity, S_0 is the signal without diffusion gradients, b_i is the b value resulting from diffusion gradients applied along direction i, and ADC_i is the ADC along this direction. Measurement of the signal intensity decay as a function of b value therefore allows straightforward calculation of the ADC.

In addition to altering the magnitude of the ADC, the presence of cell membranes and other objects that hinder diffusion can cause molecules to diffuse more easily in certain directions and less easily in other directions. For example, in the white matter of the brain, the myelin sheaths that cover the lengths of the axons act as barriers to diffusion, so that water diffuses easily in directions parallel to the white matter fibers and much less readily in directions perpendicular to the fibers. Therefore, the ADC value measured in a region of white matter depends on the direction of the measurement. Although this diffusion anisotropy of water in biological systems complicates the characterization of diffusion, it also provides useful structural information. In order to properly describe anisotropic diffusion in three dimensions, a 3 × 3 diffusion tensor is required to replace the scalar ADC [37]. From this tensor, quantitative measurements of diffusion anisotropy can be made, and parameters such as the fractional and lattice anisotropy indices can be used to summarize the degree of anisotropy [38]. In addition, the eigenvectors of the tensor can be used to determine the principle axis of diffusion, and in white matter fibers this signifies the direction of the fiber tracts. Based on this information, it is possible to perform fiber tracking by continuously following the direction of the principle eigenvectors from voxel to voxel, and thus infer fiber connections between different regions of the brain [39].

Perfusion Imaging

Perfusion (or CBF) is defined as the quantity of blood delivered to the capillary bed of a region of tissue in a certain period of time. Its units are milliliters of blood per 100 g of tissue per minute. It is important to distinguish between perfusion and bulk blood flow as seen by angiography/venography (which occurs along major arteries and veins). Perfusion is blood flow at the capillary level, and is closely related to the delivery of oxygen and other nutrients to the tissue. These factors determine the energy status of the tissue. Two main MRI approaches have been developed for CBF measurement: bolus tracking and arterial spin labeling (ASL).

Bolus Tracking

A bolus of paramagnetic contrast agent (e.g. Gd-DTPA) is injected intravenously into the subject. Shortly after, the contrast agent passes through the vasculature of the brain, and causes the signal of a T_2- or T_2^*-weighted image to change, due to a difference in magnetic susceptibility between the intravascular and extravascular compartments. This signal reduction is transient as the bolus of contrast agent washes through the tissue vasculature. The passage of the bolus is relatively fast (a few seconds), particularly in small animals. In order to characterize the signal time course accurately, which is essential for the accurate quantification of CBF, it is therefore important to acquire images as rapidly as possible. The rate at which successive bolus tracking experiments can be performed is limited by the clearance rate of the contrast agent from the vasculature. Residual levels of contrast agent reduce the signal change induced by subsequent boluses and so reduce the precision of the CBF measurement, and repeated injections of contrast agents such as gadolinium are eventually limited by their toxicity [40].

In order to convert the tissue signal intensity time course during the passage of the paramagnetic bolus to maps of CBF, it is necessary to (i) know the details of contrast agent delivery to the image voxels during the time course (the arterial input function (AIF)) and (ii) have a theoretical model which allows calculation of CBF from the MR images. The AIF can be estimated by acquiring images, which contain the feeding arteries to the tissue of interest, e.g. the middle cerebral artery. However, due to the small size of these arteries (particularly in small animals), the AIF can be difficult to measure reliably. Additionally, the effects of delay and dispersion of the bolus between the artery and the capillary bed of the tissue of interest can introduce errors in the estimation of the AIF [41,42]. For these practical reasons, absolute quantification is sometimes avoided and summary hemodynamic parameters used instead (see below). However, if we assume that we can measure the AIF with a reasonable degree of accuracy, CBF quantification is possible. First, the signal intensity changes are converted to changes in the transverse relaxation rate ΔR_2^* or ΔR_2, depending on whether GE or SE imaging has been performed ($\Delta R_2^* \equiv 1/T_2^*$). It is assumed that all signal intensity changes are due to ΔR_2^*. Figure 5a shows an example of a ΔR_2^* time course from the rat brain during a bolus passage. Assuming that ΔR_2^* is proportional to contrast agent concentration, we effectively now have a dynamic measure of the amount of contrast agent present in each image voxel. Using the principles of tracer kinetics for non-diffusable

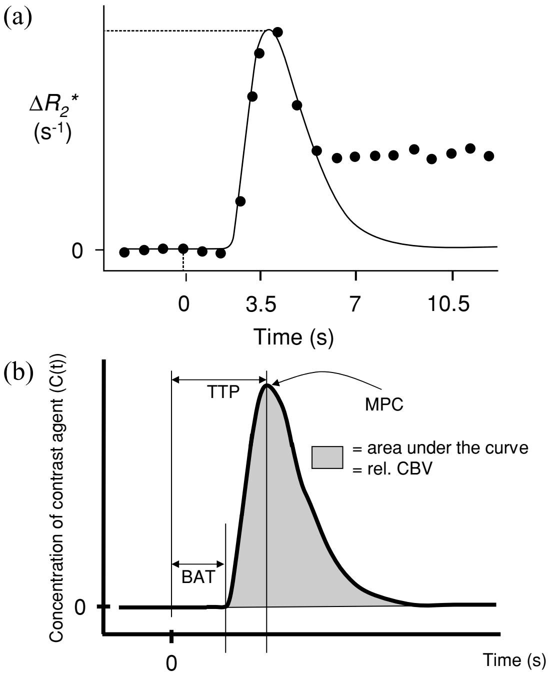

Fig. 5. (a) ΔR_2^* time course from a region of interest in the rat brain during the passage of a paramagnetic bolus. Note the increase in R_2^* during the bolus passage, caused by the transient presence of extravascular field gradients. ΔR_2^* remains elevated from the baseline value after the bolus passage due to recirculation and residual amounts of tracer in the blood. (b) Schematic representation of the concentration time curve observed in brain tissue following intravenous injection of a paramagnetic contrast agent. The summary parameters illustrated are: BAT, bolus arrival time; TTP, time to peak; MPC, mean peak concentration; rel. CBV, relative cerebral blood volume.

tracers [43–45] and assuming an intact BBB, the contrast agent concentration in each voxel (C_{VOI}) can be expressed as:

$$C_{\mathrm{VOI}}(t) = \left(\frac{\rho}{k_H}\right)\mathrm{CBF}(\mathrm{AIF}(t) \otimes R(t)), \qquad (4)$$

where $\otimes$ denotes a mathematical convolution, ρ/k_{H} is a scaling factor accounting for brain tissue density and blood hematocrit, AIF(t) is the arterial input function, and $R(t)$ is the residue function, which describes the fraction of injected tracer still present in the voxel at time t following an ideal instantaneous unit bolus injection at time $t = 0$ [41]. Using Equation (4), CBF can be calculated for each voxel. CBV can be also obtained from bolus tracking data. For an intact BBB, CBV is proportional to the normalized total amount of tracer

$$\mathrm{CBV} = \left(\frac{k_{\mathrm{H}}}{\rho}\right)\frac{\int C_{\mathrm{VOI}}(t)\mathrm{d}t}{\int \mathrm{AIF}(t)\mathrm{d}t}. \qquad (5)$$

The normalization to the AIF accounts for the fact that, independent of the CBV, if more tracer is injected, a greater concentration will reach the volume of interest. Once CBF and CBV are both known, it is also possible to calculate the average time for any given particle of tracer to pass through the tissue (the mean transit time, MTT) using the central volume theorem: MTT = CBV/CBF [46,47]. As mentioned above, an alternative to CBF quantification is to use summary parameters. The advantage of using summary parameters is that they are quick and easy to calculate, with minimal assumptions required; their disadvantage is that they do not give values for the real physiological variables CBF and CBV, and depend on experimental conditions, e.g. injection rate, vascular geometry, and cardiac output. Figure 5B illustrates the most commonly used summary parameters: bolus arrival time (BAT), time to peak (TTP), maximum peak concentration (MPC), and rel. CBV. These parameters are related to different aspects of the cerebral hemodynamics, e.g. BAT, the time after injection at which contrast agent begins to arrive in the voxel of interest, can provide information about the role of collateral blood supply when CBF is compromised. Although the use of summary parameters does not provide absolute values for CBF and CBV, it provides a useful tool for the investigation of perfusion during normal and ischemic conditions.

Arterial spin labeling

ASL is a CBF measurement method that uses magnetically labeled blood water as an endogenous tracer. It is appealing for imaging animal models of brain disease because it does not require injection of exogenous tracers and places no restriction of the number of repeat measurements that can be made in a single study. This makes ASL well suited to the monitoring of CBF during experimental time courses in animal models. The images obtained with ASL can be converted into CBF maps (with units of ml/100 g/min) as long as certain other MR parameters (such as T_1 and labeling efficiency; see below) are also measured. In ASL, perfusion-weighted images are generated by labeling inflowing blood water by inversion of its longitudinal magnetization. Two images must be acquired: one in which spin labeling is performed (the labeled image) and the other in which spin labeling is not performed (the control image). The difference between the two images is proportional to the amount of labeled blood that enters the imaging slice during the time between labeling and image acquisition, and therefore is also proportional to CBF. Spin labeling can be achieved using several alternative approaches, which has given rise to a family of ASL techniques.

The original ASL approach [48] is now generally known as *continuous* ASL (or CASL), because inflowing blood magnetization is inverted continuously over a period of several seconds prior to image acquisition. This allows an accumulation of spin labeled water as it is deposited in the perfused cerebral tissue. The measurement approach is illustrated in Figure 6a. The application of a magnetic field gradient results in a position-dependent frequency spread of the magnetization. An RF pulse of 1–3 s is applied with a frequency offset corresponding to water protons flowing through the carotid and vertebral arteries in the neck. This causes inversion of flowing spins via a process known as flow-induced adiabatic inversion [49]. Following the labeling RF pulse, an image is acquired using a rapid imaging technique (e.g. EPI). A problem associated with the off-resonance labeling RF pulse is chemical exchange of protons between water and macromolecules, which causes the water magnetization to decrease (the MT effect; see “Magnetization transfer imaging” section below). For this reason, an RF pulse with the reverse frequency offset is applied for the control image, which results in the same MT effect in the labeled and control image, so that the only difference between the images is due to the perfusion weighting.

Soon after the introduction of CASL, alternative approaches, known as *pulsed* ASL (PASL), were proposed which use shorter adiabatic inversion pulses. They have the advantage of a lower RF energy deposition than CASL due to the short (~10 ms) inversion pulses, but the disadvantage of a lower intrinsic SNR for the perfusion measurement. One of the PASL approaches is known as flow-sensitive alternating inversion recovery (FAIR) [50] and is shown in Figure 6B. This technique uses a pair of IR images, one following a slice-selective inversion pulse and the other following a non-selective (global) inversion pulse. The slice-selective IR image is flow-sensitive because the inflowing blood water magnetization is fully relaxed, and so accelerates the apparent T_1 relaxation of

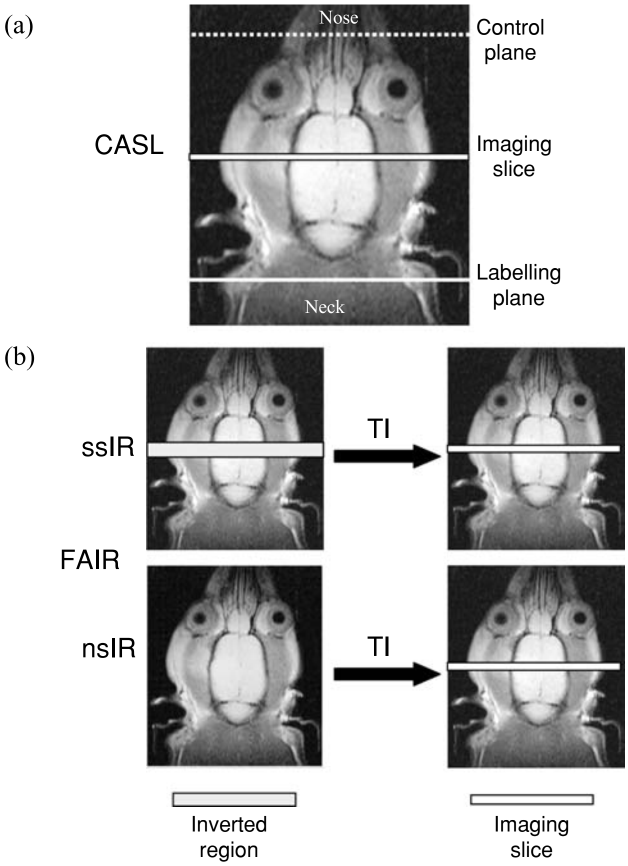

Fig. 6. (a) Continuous arterial spin labeling (CASL). Axial MR image of the rat brain showing the relative positions of the imaging slice (coronal) and the labeling and control planes. Simultaneous application of an off-resonance RF pulse and magnetic field gradient causes inversion of blood water 1H spins as they flow through the inversion plane (to produce a spin labeled image). The control plane does not intersect any major arteries and so application of an off-resonance RF pulse at this frequency causes magnetization transfer (MT) effects but not spin labeling. (b) Flow-sensitive alternating inversion recovery (FAIR)—an example of pulsed arterial spin labeling. In FAIR, a pair of images is also acquired, one following a slice-selective inversion (upper) and the other following a non-selective inversion (lower). The difference between the images is caused by the difference in the magnetization state of the inflowing blood water and is therefore directly proportional to CBF.

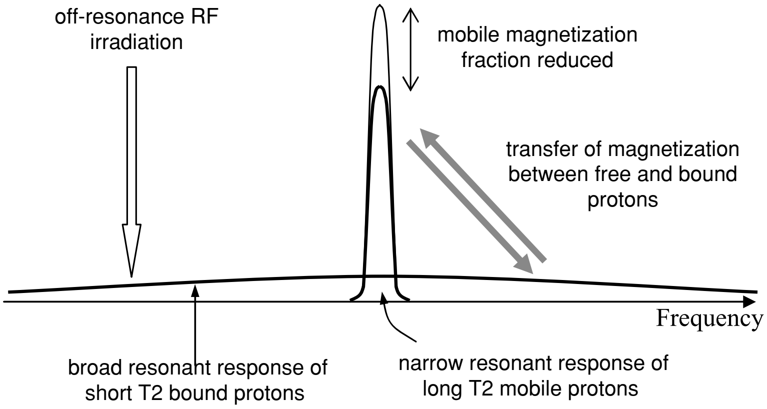
the tissue into which it flows. In the non-selective IR case, both tissue and inflowing blood magnetization are inverted, resulting in negligible flow sensitivity. Since the same inversion time is used in both the slice-selective and non-selective acquisitions, the signal from the static tissue is the same in both, but a difference between the images is observed in the presence of flow.

Perfusion can be quantified using ASL images and some additional information such as T_1. For a full description of the principles see [36,51], but in general the signal intensity in the ASL difference image (control–labeled) is directly proportional to CBF. An important factor that affects the accuracy of CBF quantification is a parameter known as the transit time. Following spin inversion, blood water travels through the vascular tree until it reaches the capillary bed and exchanges into the cerebral tissue. During this time (the transit time), the spin label decays at a rate determined by the T_1 of arterial blood. This must be accounted for in order to achieve accurate CBF quantification. Transit time effects are particularly problematic in CASL, where the labeling plane must be a minimum distance from the imaging slice to ensure that it coincides with a major artery. With PASL, transit times tend to be lower because the labeling region can be placed immediately adjacent to the imaging slice. To decrease the sensitivity to transit time effects, the sequences can be modified by inserting a post-labeling delay, which allows time for all the blood to travel from where it was labeled into the imaging region [52–54].

Magnetization Transfer Imaging

Magnetization transfer contrast (MTC) imaging [55] provides a means of probing a population of hydrogen nuclei otherwise invisible to conventional MRI [56]. These protons exist in a so-called "bound" state, i.e. their motion is restricted because they form part of either macromolecules, or water molecules restricted within the hydration layers around macromolecules. Such protons exhibit very short T_2 relaxation times (<100 μs) which implies



off-resonance RF irradiation
mobile magnetization fraction reduced
transfer of magnetization between free and bound protons
Frequency
broad resonant response of short T2 bound protons
narrow resonant response of long T2 mobile protons

Fig. 7. Schematic diagram showing the origin of magnetization transfer contrast. Off-resonance RF irradiation affects directly only the broad resonance of the bound proton fraction. Exchange ("transfer") of magnetization between this bound proton fraction and the mobile water fraction causes a concomitant reduction in the mobile water magnetization, and hence a reduction in MR image intensity.

total signal decay before acquisition can commence even with short-TE standard SE MRI methods.

There is an inverse relationship between T_2 and the range of frequencies over which protons respond to RF excitation: protons in the "bound" fraction exhibit very short T_2s and consequently have a broad resonance width (~20 kHz) in the frequency domain. On the other hand, bulk water protons possess long T_2s with a correspondingly narrow (~10 Hz) frequency domain resonance (Figure 7). This difference can be used to perturb the bound fraction independently from the bulk protons. If continuous RF irradiation is supplied at a frequency offset (typically by 1–5 kHz) from the central resonant frequency, the magnetization of the bound protons will be reduced by saturation, while, in the absence of exchange, the bulk water pool remains unaffected. However, there is generally a significant exchange of magnetization between the two proton fractions, either by direct chemical exchange or by magnetic interactions. Since the bound proton magnetization has been reduced by the off-resonance irradiation, such exchange leads to a consequent reduction in both the magnitude of the observable bulk water magnetization and its effective T_1 relaxation time. The size of the signal decrease depends upon both the relative sizes of the two fractions and upon the rate of magnetization exchange. Since both of these factors may be influenced by tissue pathology, MTC imaging is uniquely sensitive to certain disease processes.

MTC imaging is commonly achieved semi-quantitatively by collecting an image (S_s) in which acquisition is preceded by a long (~3 s) saturating off-resonance RF pulse. A second image (S_0) is then acquired without a pre-saturation pulse and the magnetization transfer ratio (MTR) calculated as:

$$\mathrm{MTR} = (S_0 - S_\mathrm{s})/S_0 \times 100\% \tag{6}$$

A high MTR signifies the presence of a significant proton pool associated with macromolecules or cellular microstructure *and* a significant exchange of magnetization between these protons and those of the bulk water. Reduced MTR suggests a disruption of the tissue microstructure. A common example of the utility of MTC is the depiction of the pathological disruption of white matter due to demyelination, e.g. in multiple sclerosis.

In order to reduce imaging time and possibly to overcome certain hardware limitations, selective saturation of the bound fraction may also be achieved by pulsed methods. Here GE images with short TR are obtained with each excitation pulse preceded by a short (~10 ms) off-resonance pulse [57]. If the repetition time is sufficiently short compared to the T_1 of the bound pool, an equilibrium saturation of these spins is established after a number of cycles. In practice, the magnitude of the MTC effect measured is dependent upon the duration, intensity, and frequency offset of the off-resonance pulses, and caution is therefore required in the comparison of MTC imaging results obtained using different implementations.

Conclusions

In summary, MRI provides an array of quantitative techniques sensitive to a range of biophysical parameters. Within a single scanning session, several of these methods can be applied, yielding images with different, complementary contrasts and providing a rich understanding of the physiological microenvironment. The application of these techniques in suitable animal models of disease may greatly enhance our knowledge of brain pathologies, provides improved diagnostic and prognostic measures, yield insight into basic mechanisms of cellular injury, and, by providing non-invasive biomarkers of disease progression, greatly facilitate the assessment of novel therapeutic strategies.

Acknowledgments

The authors would like to thank Romina Aron-Badin, Mankin Choy, Neil Harris, and Rick Dijkhuizen for their contribution of images for the manuscript. We also acknowledge the Wellcome Trust and the BBSRC for their support of the work carried out at the Radiology and Physics Unit of the Institute of Child Health, and the Wellcome Trust High Field MR Research Laboratory, University College London.

Introduction

MRI of intact animals was first employed in the 1970s. With the advent of dedicated animal scanners, the use of MRI for *in vivo* animal studies has mushroomed, and currently thousands of papers are published every year. Though a wide variety of laboratory animals is used, including monkeys, songbirds, and piglets among many others, the majority of MRI studies concerns rodent models of disease. In particular the use of mice has increased substantially over the past few years due to the development of a large range of transgenic mouse models. This chapter is dedicated to the use of MRI in small animal models of brain disease, and will describe some of the practical issues surrounding the use of MRI, and review the role of MRI in investigating the pathophysiology of the most common neurological disorders.

Practical Issues

Signal-to-noise

The size difference between humans and rodents is about a factor 10–20. To achieve a spatial resolution equivalent to that obtained in clinical imaging, this means that the voxel volume has to be reduced at least a factor of 10^3, implying in turn that the sensitivity has to be increased correspondingly to obtain a similar signal-to-noise-ratio (SNR). Much of the sensitivity can be gained by using RF receiver coils that are optimized for the size of the animals. Further sensitivity can be obtained by increasing the magnetic field strength; currently, horizontal small animal MRI systems with field strengths up to 11.7 T are commercially available. A third possibility to improve SNR is to increase the acquisition time up to several hours, which currently is used mostly for anatomical imaging of either *in vivo* or fixated animals.

Probes

To acquire data within the MR scanner, the animal should be immobilized in a non-magnetic probe with ear and bite bars, allowing the head to be positioned reproducibly relative to the gradient coils to attain the correct imaging slice or region of interest. Several MR-compatible stereotaxic frames have been designed to permit reproducible positioning in the scanner for repeat measurements. In MR magnets with a small bore, the use of ear and bite bars may not be possible, in which case the skull may be glued directly to the probe to reduce movement artifacts [1].

Temperature control is commonly attained through the use of either warm air blown over the animal, an electrically heated mat, or a warm water jacket or mat. Animals are readily anaesthetized via administration of anesthetics through a nose cone for spontaneously breathing rodents, intraperitoneal injection, or mechanical ventilation (see below). Physiological monitoring of cardiac and respiration rate may be performed simultaneously using implanted chest electrodes [2] or conventional EE electrodes in combination with an air pressure cushion to monitor respiration. Blood pressure is conventionally monitored using an intra-arterial line or, more recently, a piezoelectric pulse transducer [3]. Intravenous lines may be inserted for blood gas measurements or administration of drugs.

With the recent development of numerous transgenic mouse models, the demand for high-throughput phenotypic and physiological screening of large numbers of animals has soared. Therefore, probes have been designed that can hold several mice at the same time, with individual decoupled and shielded transmitter and receiver coils, anesthetics, and physiological monitoring [4]. Up to 16 mice can thus be measured in a single session.

To record EEG signals during an MRI experiment, silver or tungsten electrodes can be implanted. Alternatively, non-magnetic graphite electrodes, which reduce susceptibility effects, may be used EEG [5]. Gradient switching causes large artifacts on all EEG measurements, and data

Graham A. Webb (ed.), Modern Magnetic Resonance, 801–821.
© 2008 *Springer.*

need to be filtered to remove these. This is particularly problematic when using ultra-fast imaging sequences, where there may not enough undisturbed time intervals for a usable EEG recording.

Anesthesia

Correct anesthesia becomes very important when studying physiological processes, since many anesthetics may interfere with the processes under investigation. The most common route of application is inhalation via a nose cone. This approach allows close control of the depth of anesthesia, which can be assessed from the respiration and cardiac rate. However, when using spontaneous breathing, there is little or no control of blood gases, since CO_2 is often accumulated due to respiratory depression; mechanical ventilation may be used to control oxygen and carbon dioxide levels.

Alternatively, the animal can be anaesthetized for up to several hours using an injectable anesthetic, either intravenous or intraperitoneal. This method is very straightforward, but the depth of anesthesia is difficult to control, and one may need to give top-up injections while the animal is in the magnet.

The choice of anesthetic should depend on the physiological problem in question, as different substances may have distinctly different effects on systemic blood pressure, cerebral blood flow (CBF), cerebral oxygen consumption, and receptor function [6]. The method of choice in most laboratories is inhalation of isoflurane with oxygen/air or an oxygen/nitrous oxide mixture. It is important to note that isoflurane reduces the heart rate and blood pressure due to vasodilatation, which in turn influences CBF and therefore also the blood oxygenation level dependent (BOLD) effect (see Chapter 3). Reports have shown neuroprotection after stroke due to pre- or peri-ischemic administration of isoflurane and several other anesthetic agents [7,8].

In some cases, e.g. for functional MRI, maintenance of the BOLD effect and neuronal activity is of prime importance. For those studies injectable α-chloralose is routinely used, because it maintains a stable CBF and cortical activity; however, this agent is usually only used for terminal experiments. Nevertheless, functional response is always greater in a conscious animal, and some groups actually train conscious animals to remain immobile in a stereotaxic frame for several hours [9,10]. Obviously, extensive training is required to adapt the animals to the frame and to the noise levels during the experiment.

Selection of Animal Models

Adaptations may need to be made to an animal model to make it usable for MRI measurements. This is especially true when there is an interest in the very acute stages of disease. For example, the introduction of new MR imaging techniques such as diffusion-weighted imaging (DWI) allowed the investigation of a stroke within minutes of the initial event, which led to the modification of animal models to induce ischemia by remote occlusion whilst the animal was inside the MRI scanner [11]. The following section will discuss the specific MRI adaptations to models of cerebral ischemia, since this is the area where most developments have occurred.

Focal Ischemia Models

Most remote occlusion models are based on the Koizumi model for middle cerebral artery occlusion (MCAO) using a silicone rubber cylinder attached to a thread inserted through the internal carotid artery [5,11–14]. These remote occlusions are essential to investigate the hyperacute MR changes post-occlusion, and also to allow a direct comparison of pre- and post-occlusion image data [11,14]. This is not a trivial experiment, but as shown by Li *et al*., successful occlusion could be achieved in 88% of animals studied. Lythgoe *et al*. developed a model based on the intraluminal suture method, which uses an undersized suture to produce a partial obstruction of the MCA and a moderate reduction in CBF throughout the MCA territory [15]. Recently, a remote model was developed in which the MCA and both common carotid arteries (CCA) can be (partially) occluded and de-occluded using a small bronze hook placed around the MCA via a small craniotomy, and snares of bronze wire placed around the CCAs. This model is only suitable for terminal experiments, but is extremely reproducible and allows for careful manipulation of perfusion [16].

Apart from the suture and snare model, there are several thromboembolic occlusion models in which an embolus is injected via a catheter [17–19]. The embolus can be either artificial (e.g. microspheres) or biological (e.g. homologous blood clots). These models can be used in-bore and are more representative of the clinical situation, though they tend to be less reproducible. In the case of blood clots, reperfusion can be established by rt-PA treatment, but reperfusion is slow and variable.

Global Ischemia Models

Cardiac arrest has been extensively employed for the study of the pathological consequences of global ischemia and reperfusion [20]. Fischer *et al*. have extended this work for MR and demonstrated the feasibility of resuscitation following cardiac arrest within the magnet [21]. In 1979, Pulsinelli and Brierley introduced the four-vessel occlusion model of reversible ischemia in rats [22,23]. Briefly, on the day before the experiment, atraumatic clasps are placed loosely around both CCAs and the vertebral arteries are electrocauterised. Global ischemia is induced by tightening the sutures around the CCAs. This technique has been used quite extensively with MR for both single and repeated occlusions [24] and also to produce graded ischemia [25]. Global insults may also have both a hypoxic and ischemic component. With the aim of modeling human birth asphyxia, Thornton *et al*. have described a hypoxic/ischemic piglet model using inflatable cuffs around both CCAs combined with a decreased oxygen level [26].

The remaining sections in this chapter give an overview of some of the possibilities for MRI investigations of cerebral pathology in experimental animal models.

Cerebral Ischemia

Cerebral ischemia occurs when the blood supply to some or all brain regions is interrupted due to arterial occlusion, vascular disruption, or heart failure. The resulting reduced perfusion leads to oxygen deprivation, energy failure, and ultimately cell death. The use of MRI in experimental stroke research includes both diagnostic applications and prediction of outcome [27]. Some of the most important topics are the investigation of the underlying processes that lead to cell death [28], defining and understanding the concept of the penumbra [29] as a possible salvageable region, and possible therapies for the treatment of stroke [30,31].

Perfusion During Ischemia

Cerebral blood flow and cerebral blood volume (CBV) can be assessed using perfusion imaging. These measurements are based on either a susceptibility change in the vascular bed due to the passage of an exogenenous contrast agent (dynamic susceptibility contrast (DSC) enhanced MRI), or on the blood water pool as an endogenous perfusion marker (arterial spin labeling (ASL)), see Chapter 3 for details. Early DSC experiments in rat and cat models of focal cerebral ischemia demonstrate an absence of contrast agent in the ischemic core of the lesion [32,33]. Numerous other studies have followed, showing the spatial diversity within the ischemic tissue [34,35]. The relation between CBF and CBV can be used to assess hemodynamic responses such as vasodilatation [36,37], whereas the bolus peak time provides information on the arterial transit time, which may relate to collateral blood supply to the ischemic area [38]. This work using DSC-MRI has been complemented by studies using non-invasive ASL techniques for the quantitation of CBF in animal models [39]. Although these techniques have a low SNR compared to DSC-MRI, the non-invasive nature and the possibility to perform serial measurements make them an attractive tool. Acute cerebral ischemia has been characterized by serial CBF measurements in permanent and reperfusion stroke models [40–43].

A direct translation of perfusion rates into potential tissue damage is difficult, for several reasons. Firstly, CBF quantification is not always straightforward due to unknown parameters like the arterial input function and arterial transit times. Secondly, CBF thresholds appear to be different for different cell types and brain regions [44]. Thirdly, CBF values tend to vary over time, and the actual tissue damage strongly depends on the duration of ischemia, and on the level of perfusion throughout the insults and during reperfusion. Therefore other parameters have been explored that are more directly influenced by the physiological state of the tissue, including diffusion and relaxation.

Diffusion During Ischemia

The first DWI studies of permanent ischemia demonstrated, that following occlusion of the MCAO, the ADC decreases and the corresponding ischemic lesion in both rat and cat is visible within minutes and expands primarily during the first 2 h [45]. Although the lesion size has nearly fully evolved at 2 h, the ADC value continues to decrease for a period of up to 4–6 h following MCAO to 40% of control values [46], with some studies reporting the lowest ADC values at 24–48 h (40–50% of control) [47]. In the chronic stages of cerebral ischemia, the ADC of water exhibits a different pattern. Approximately 24–48 h after a vessel occlusion, the ADC starts to rise again and slowly pseudo-normalizes at 3 days [48]. Following this, a subsequent increase in the diffusion of water above that of the ischemic control can be observed after 1 week [46]. The elevated ADC of tissue water is associated with cellular lysis or the loss of cellular barriers, combined with an excessive accumulation of edematous water [49].

Interestingly, in the periphery of the lesion, a diffusion–perfusion mismatch can be observed, i.e. perfusion deficits not great enough to cause energy failure may go unnoticed on DWI. A cat model of hypoperfusion shows the same pattern, with diffusion-weighted images showing no evidence of abnormality in the territory of the occluded MCA, whereas the DSC-MRI blood flow measurements show decreased CBF throughout the MCA region [50]. By combining DWI and CBF data, three different tissue areas can be identified following an ischaemic insult: areas with normal perfusion and diffusion, denoting normal tissue; a region in which there is a concomitant diffusion and perfusion decrease, corresponding to a severely compromised region; and tissue that has a CBF decrease without diffusion changes corresponding to a region of hypoperfusion, the so-called diffusion-perfusion mismatch [41]. The relation between these areas and the core and penumbra of a stroke lesion is discussed below.

The Penumbra

The term *penumbra* was introduced to designate a zone of brain tissue with moderate ischemia and impaired neuronal function, with the neuronal paralysis being fully reversed upon reperfusion [51]. Currently the term has a wider definition and is used to describe a region of ischemic tissue peripheral to the core where viable neurons may be found, and thus may be potentially salvageable with suitable intervention or therapy [29,52]. As for CBF, ADC thresholds have been proposed, below which irreversible tissue damage would occur [53], but it is recognized more and more that, especially in the case of ischemia-reperfusion, the pathology is too complicated to justify the same threshold in all cases. Penumbral zones can be delineated using several different imaging modalities, each of which have definitions that rely on the underlying mechanisms of that technique [29]. The region of signal intensity change in DWI corresponds closely to the region of peri-infarct acidosis, but also encompasses the area of ATP depletion (infarct core). Therefore, it was postulated that the outer margin of the DWI visible lesion corresponds with that of the penumbra [54]. However, this is only part of the picture, as it is now acknowledged that regions of DWI change that normalize on reperfusion may proceed on to infarction at a later time point [55,56] and that the areas of so-called diffusion–perfusion mismatch need to be considered as well [57]. Because tissue damage is dependent on residual flow and duration of ischemia, the ischemic penumbra characterizes a transient condition that may extend in time to hypoperfused surrounding tissue. A recent study of global transient ischemia showed that the striatum exhibited a prolonged and gradual secondary ADC decrease after reperfusion, suggesting delayed cell death via a gradual process long after the initial insult (Figure 1) [58].

In human studies it has long been recognized that diffusion in organized tissue is anisotropic, which lead to the development of diffusion tensor imaging (DTI). Early reports demonstrate ADC anisotropy in cortical gray matter and in white matter in a rat model of cerebral ischemia, showing that diffusion encoding in one direction only results in poor lesion delineation [1,59]. Sotak *et al*. showed increased anisotropy during the first hours of permanent focal ischemia in the rat, combined with a reduced overall ADC [60].

At later stages, these characteristics are reversed, i.e. ADC is elevated and anisotropy reduced, reflecting the loss of cellular barriers [60,61].

Relaxation Contrast During Ischemia

During the last few years, animal studies have demonstrated that several MRI parameters provide additional information to the now clinically implemented T_2, diffusion and perfusion measurements.

Early changes in T_2 values have been reported in conditions of ischemia [41,62] and oligaemia [63]. In the latter studies of cerebral ischemia, two patterns were observed following an initial T_2 decrease: (i) T_2 values remained depressed throughout the study without an ADC change, indicating a mild hypoperfusion condition [41,62]; (ii) T_2 and ADC values are decreased throughout the study, indicating a severe hypoperfusion condition [41,64]. Further, early detection (within 15 min) of ischemia [41] and oligemia [63] are possible using the MRI parameter T_1. The underlying mechanism for this change is still unclear, but may depend of tissue oxygenation status. These data highlight that changes in T_2 and T_1 and are not always related to vasogenic edema and early changes in these parameters may provide information as to the pathophysiological nature of ischemia or oligaemia. Kavec *et al*. used both short and long echo times in a CPMG sequence to distinguish changes in BOLD contrast from intrinsic relaxation changes in the tissue, which they argue might be a marker for irreversible tissue damage [65].

Gröhn *et al.* [66] have demonstrated early detection of irreversible cerebral ischemia in the rat using a parameter known as $T_{1\rho}$ (T_1 in the rotating frame), which probes specific spin populations taking place in the macromolecules or in the macromolecular-water interface.

During the last few years, new approaches have been adopted to image molecular targets using specific contrast agents. A novel contrast agent (Gd-DTPA-sLe(x) A) has been designed by Barber *et al*. to bind to activated endothelium. Injection of the agent after focal ischemia in mice resulted in reductions in T_1 in the ipsilateral hemisphere that were unrelated to blood–brain barrier breakdown [67]. Several paper have been published on stem cell tracking after stroke [68,69]; a more detailed review can be found in Chapter 8.

Functional Imaging After Ischemia

BOLD MRI is sensitive to changes in regional tissue oxygenation status [70], making it useful to monitor acute deoxygenation following induction of ischemia as well as reoxygenation after reperfusion [64]. BOLD MR signal intensity, obtained by T_2*-weighted MRI, drops immediately upon the onset of ischemia, and rises when reflow occurs. A transient overshoot in signal intensity during reperfusion has been described and may reflect post-reperfusion hyperemia [71]. These hemodynamic responses indirectly report on local changes in CBF, CBV, and oxygen extraction fraction and their individual contributions cannot easily be distinguished.

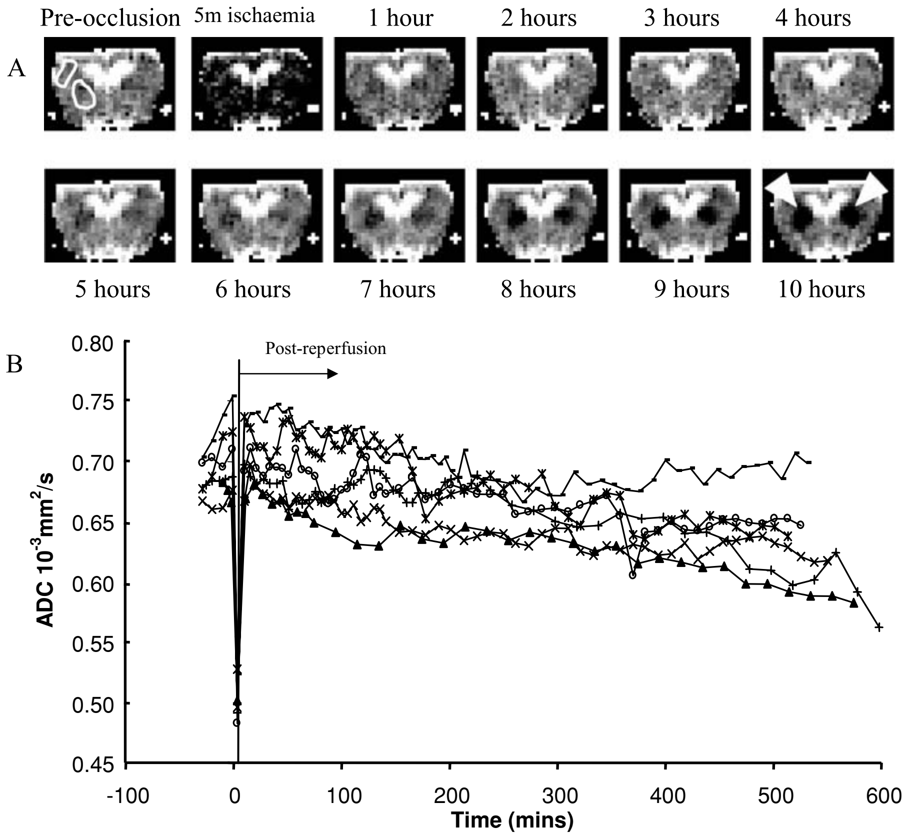

Fig. 1. (A) Coronal ADC maps at the level of the bregma before, during, and after 5 min of ischemia and reperfusion. Following bilateral occlusion of the CCA in the gerbil there was a decrease in the ADC, on reperfusion there was a recovery to baseline values, with a subsequent gradual decrease in ADC that was confined to the lateral portion of the striatum (white arrows). Representative ROIs are placed on the first image. (B) Temporal evolution of the ADC values in basal ganglia regions. Time = 0 min is the point of occlusion and at time = 5 min, reperfusion was initiated. Note the gradual decline in ADC values in the basal ganglia. Courtesy of M.F. Lythgoe.

Stroke patients show some functional recovery over time, which is commonly thought to be associated with brain plasticity. Recent BOLD MRI studies have demonstrated changes in activation patterns following a stroke [72,73]. With the use of behavioral tests and MRI in a rat stroke model, Dijkhuizen *et al.* [73] showed that unilateral stroke induced acute dysfunction of the contralateral forelimb, which significantly recovered at later stages. A further study suggests that the degree of shift of activation balance toward the contralesional hemisphere early after stroke increases with the extent of tissue injury and that functional recovery is associated mainly with preservation or restoration of activation in the ipsilesional hemisphere [74].

Tissue Signature Modeling

In deciding whether tissue is suitable for treatment, it is necessary to distinguish compromised yet recoverable from permanently damaged tissue. Thus, various combinations of MRI parameters may provide more reliable MRI tissue signatures and several groups have developed methods to distinguish degrees of tissue damage and to predict final outcome.

Jiang *et al*. have developed a multiparameter cluster analysis model of acute ischemic stroke using T_2 relaxation times and the diffusion coefficient of water (ADC_w). Significant correlations were obtained between MRI signatures at different time points, specified by values of

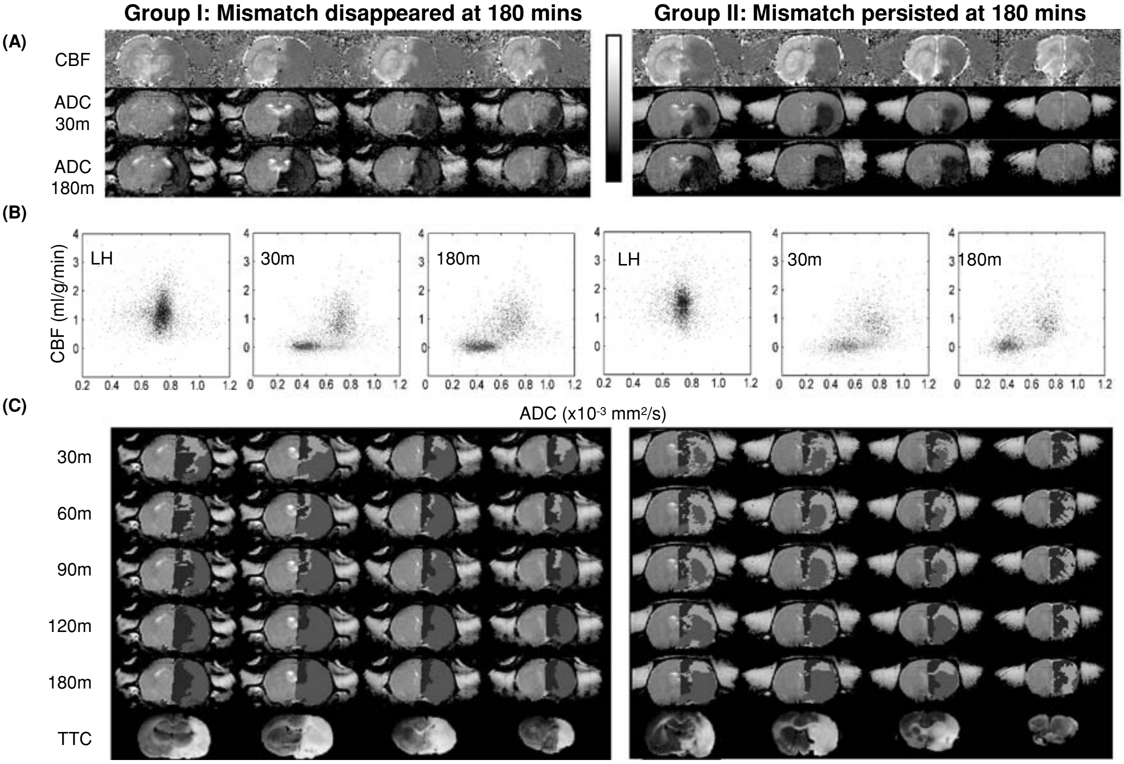

Fig. 2. Representative data from a stroke rat with "perfusion-diffusion" mismatch disappeared at 180 min after ischemia (Group I, left) and another rat with some "perfusion–diffusion" mismatch remained at 180 min (Group II, right). (A) Cerebral blood flow (CBF) maps, and ADC maps at 30 and 180 min. The grayscale bar: ADC ranges from 0 to 0.001 mm^2/s, CBF ranges from -1 to 2 ml/g/min. (B) CBF-ADC scatterplots of the normal left hemisphere at 30 min, ISODATA cluster analysis results of the right hemisphere at 30 and 180 min. (C) Pixel clusters from the CBF-ADC scatterplots were overlaid on the image space at 30, 60, 90, 120, and 180 min. In the right hemisphere, blue, green, and red are assigned as "normal," "perfusion–diffusion" mismatch, and "ischemic core" clusters, respectively. TTC slides at 24 h are also shown. Reprinted with permission from Shen *et al*. [77]. (See also Plate 66 on page XLV in the Color Plate Section.)

ADC_w and T_2, and histopathologic measurements of lesion area obtained at 1 week, implying that the final outcome of ischemic cell damage can be predicted from the MRI tissue signature at early timepoints [75]. Similar conclusions were drawn by Jacobs *et al*., who used a vector tissue signature model that uses T_2, T_1, and DWI for segmentation and characterization of ischemic tissue [76]. Shen *et al*. used an iterative-self-organizing-data-analysis-algorithm dynamically track ischemic tissue fate on a pixel-by-pixel basis during the acute phase. Clusters were overlaid on the CBF-ADC scatterplots and provided an accurate prediction of tissue fate (Figure 2) [77]. A predictive algorithm combining perfusion and diffusion data has been used successfully to assess the effect of stroke therapy, showing that delayed rt-PA treatment in a rat embolic stroke model decreased the amount of tissue expected to proceed to infarction [78,79].

Spreading Depression

Spreading depression (SD) is a term for spreading cortical depolarization and depression of electroencephalographic (EEG) activity. Under normoxic conditions, SD occurs during migraine aura, where it precedes migraine pain but does not damage tissue. During stroke, epilepsy and head trauma, however, SD can arise repeatedly near the site of injury and may play a key role in the expansion of neuronal damage [80,81]. During SD the metabolic rate of the tissue increases in response to the greatly enhanced energy demands of the activated ion exchange pumps [82]. In the penumbra, flows are suppressed and as a result, the increased metabolic demand is not compensated by an increase in oxygen and glucose [83]. Eventually ATP stores will be depleted, followed by the cascade of pathophysiological events leading to tissue damage.

The first MRI study was published by Latour *et al*., who elicited SD in rats by topical application of potassium chloride to the exposed cortex. Using repetitive ADC measurements, he showed that the ADC declines within 30 s and recovers to the normal value within the next 30 s. The region of decreased diffusion was shown to be 2 mm in size and to move in the cortex, away from the point of application, with a uniform velocity of about 3.3 mm/min [84]. Another approach, reported by Gardner *et al*. in the same year, is the use of gradient echoes to demonstrate propagating waves of SD, which were initiated by remote perfusion with KCl. Within 2 min of application of KCl, they observed a zone of increased signal intensity on the MR image, with a size and propagating velocity similar to the Latour study. The increased signal intensity in gradient echo images has been attributed to an increased level of oxygenation within the venous blood during SD [85,86]. Rother *et al*. used serial DWI during remote MCAO to map transient ADC decreases post MCAO. Transient ADC changes were detected in six of seven rats post MCAO and subsequent renormalization within about 3 min. These ADC changes propagated bidirectionally away from the ischemic core and occurred in ischemic areas characterized by moderately decreased tissue perfusion, suggesting these are waves of SD [87]. These results would imply that SD does play a role in the pathophysiology of stroke. A more in-depth study into the effect of SD on ischemic injury used a combination of ADC imaging and electrophysiology to assess ischemic lesion volumes after MCAO and KI application as a function of the number and duration of SD episodes. The ischemic region increased significantly if SD was present, supporting the hypothesis for a causative role of SD in extending focal ischemic injury [88]. Dijkhuizen *et al*. showed that the ischemic lesion size was dependent on the total duration of tissue depolarization and not to the frequency of depolarizations [89].

SD after transient MCAO in ratsis prolonged or inhibited by hypothermia as measured by ADC imaging [90]. However, they also reported that the maximum ADC decrease within SD was greater than for normothermia, which currently remains unexplained.

With respect to role of SD in migraine, Bradley *et al*. investigated whether DWI could detect the effects of the antimigraine drug sumatriptan and the novel anticonvulsant tonabersat in the cat brain. Supporting previous findings, sumatriptan did not affect the numbers of events, the duration or the SD velocity; tonabersat significantly reduced SD event initiation and duration and increased primary event velocity. However, both drugs significantly decreased, by >50%, the spatial extent of the first KCl-evoked SD event, and sumatriptan significantly increased event propagation across the suprasylvian sulcus, confirming the role of SD in migraine [91].

Manganese-enhanced MRI has been reported as a new visualization method for neural activation. Aoki *et al*. used this method to visualize anoxic depolarization and to compare regional differences between manganese accumulation and decreased ADC. They found that the enhanced region was much smaller than the area which was detected as having a reduced ADC, and speculate that the manganese-enhanced region is caused by some ischemic cascade such as Ca^{2+} influx related to anoxic depolarization in the ischemic core [92].

Epilepsy

The epilepsies are a group of disorders with a wide range of presentations and multiple etiologies [93]. In order to model such a varied condition, several different and quite diverse approaches have been developed, and currently no single model is appropriate for all conditions. In 1972, Purpura *et al*. produced a comprehensive review covering many experimental models, which still remains a useful guide to the various methods used to induce epilepsy or seizures [94]. Clinically, the epilepsies are characterized by spontaneous recurrent epileptic seizures, which are caused by generalized paroxysmal or partial (focal) discharges in the brain [93].

Animal Models

Animal models of *generalized seizures* include animals affected by genetic reflex epilepsy [95], such as the baboon, *Papio Papio* [96], mouse (DBA/2J) [97], genetically epilepsy prone rats (GEPRs) [98], rabbits [99], and the Fayoumi chicken [100]. In these animals, seizures may be induced by intermittent light stimulation, noise, movement, and stress [94,95]. Another animal model that exhibits generalized seizures is the maximal electroshock model. This model is predominately used to test possible therapies for primary and secondary generalized epilepsies [101].

Models for *simple partial seizures* include focal microapplication of topical convulsants such as penicillin [95], bicuculline [102], picrotoxin [103], strychnine [104], and kainic acid [105] on the cerebral cortex. Another method uses acute direct repetitive electrical stimulation, which can lead to discharges that persist for seconds or minutes after the electrical stimuli cease [106].

Chronic seizure models develop following the application of metals such as alumina hydroxide, cobalt, tungsten, or zinc [107,104]. Spontaneous recurrent seizures may appear 2 months after the injection, and persist in some cases for several years [107]. Models of *complex partial seizures* may be induced via injection of tetanus toxin into the hippocampus; seizures first occur at 1–7 days post-injection and then chronically [108,109]. Administration of kainic acid, an excitotoxic analogue of L-glutamate, leads to spontaneous recurrent seizures and hippocampal damage even when injected systemically [110,111]. A now widely used animal model for the study of epileptogenesis is the kindling model. One technique for induction is regular stimulation of chronically implanted electrodes until spontaneous generalized seizure is achieved [112,104]. The ubiquitous lithium-pilocarpine model presents with status epilepticus (SE) usually within 1–2 h of injection, which may last for up to 12 h and then finally progresses to spontaneous recurrent seizures [113]. Animal models of SE may be produced via techniques such as the administration of chemical convulsants [114–116] or electrical stimulation [117,118].

Early MRI Studies of Epilepsy

Although the majority of experimental epilepsy research has been performed outside the neuroimaging field, there has been increasing interest in the use of MRI following some early and promising nuclear magnetic resonance spectroscopy investigations, and more recently imaging studies. Broadly speaking the present goal of imaging is to characterize both the metabolic derangement and brain injury associated with seizures, using functional (spectroscopy, diffusion and perfusion imaging) and structural (T_1 and T_2) neuroimaging. The first *in vivo* MR experiment in an animal model of seizures revealed a decrease in phosphocreatine, without a change in adenosine triphosphate (ATP) levels during seizure activity [119]. This and several other spectroscopy studies demonstrated the feasibility of combining animal models of epilepsy and NMR [120,121]. Non-invasive imaging of animal models of epilepsy started in the early 1990s. A preliminary imaging study provided evidence for tissue damage detectable by MRI following kainate injection in the rat brain. Although the procedure did not induce seizures, the T_1-weighted strategy provided better image contrast for the kainic acid lesion than the T_2 approach, and the diffusion-weighted images showed improved contrast for edematous tissue [120,122]. Another early study demonstrated blood flow changes via the MR blood oxygenation level dependent (BOLD) contrast in the kainic acid model of seizures in rats. Increases in blood flow were associated with minor behavioral seizure signs, but as seizure activity progressed, signal intensity remained near baseline, possibly due to increased neuronal activity (as observed on EEG), which subsequently increased oxygen extraction thereby normalizing the BOLD response [123]. This preliminary study demonstrated the potential of fMRI for investigating hemodynamic changes associated with seizure activity, yet it was many years before further fMRI studies would be performed (see below).

Diffusion Imaging in Epilepsy

In 1993, Zhong *et al.* [124] published an influential paper using DWI to investigate changes associated with SE. Following intraperitoneal injection of bicuculline in the rat, the apparent diffusion coefficient (ADC) of water in the brain decreased 14–18% during seizures. No changes occurred in T_1 or T_2. This result demonstrated that during a seizure the ADC changed in a similar fashion to that reported in ischemia [27], but under different circumstances as the blood flow is increased and the ATP stores are only modestly reduced. This finding was also confirmed during flurothyl exposure, which is thought to act on the sodium channel to alter the responsiveness of the GABA and glutamate receptors, causing convulsions at high doses [125] and during frontal cortical electroshock [126]. Magnetic resonance spectroscopic imaging together with T_2- and DWI was first used in experimental epilepsy to investigate selective hippocampal and piriform cortex damage following kainate-induced SE in the rat. Decreased N-acetyl aspartate, increase lactate and decreased ADC were observed at 12 h with little evidence of histological and T_2-weighted changes, and it was suggested that such changes may provide a diagnostic measure for evaluating risk of neuronal damage after SE [121].

More recently, diffusion studies have provided novel approaches to investigate brain microarchitecture. It has been suggested that using q-space imaging after SE it is possible to distinguish neuronal tissue from early glial cell damage in a pilocarpine model [127]. DTI, an emerging technique to investigate tissue anisotropy, has recently been applied to the investigation of an avian model of epilepsy. Following photic stimulation and subsequent onset of generalized tonic-clonic seizures in the chicken, DTI revealed regional differences in the juvenile chicken compared to nonepileptic controls, but as the brains matured these differences disappeared [128]. As yet it is not known whether DTI will provide addition information to other MRI parameters and further work is necessary to understand its role in the investigation of animal models of epilepsy.

Time Course Studies in Epilepsy

The long-term temporal evolution of lesion development, investigation of epileptic activity and tissue damage are well suited to the non-invasive nature of MRI [129–131]. Early time points demonstrate ADC decreases during and after SE, and BBB breakdown (limited to the thalamus) 2 h after SE [124,132,133]. Despite differences in the models used (pharmaceutical and electrical), there is a similarity in the progression of pathology as measured by MRI. Initially there is a transient increase in T_2,

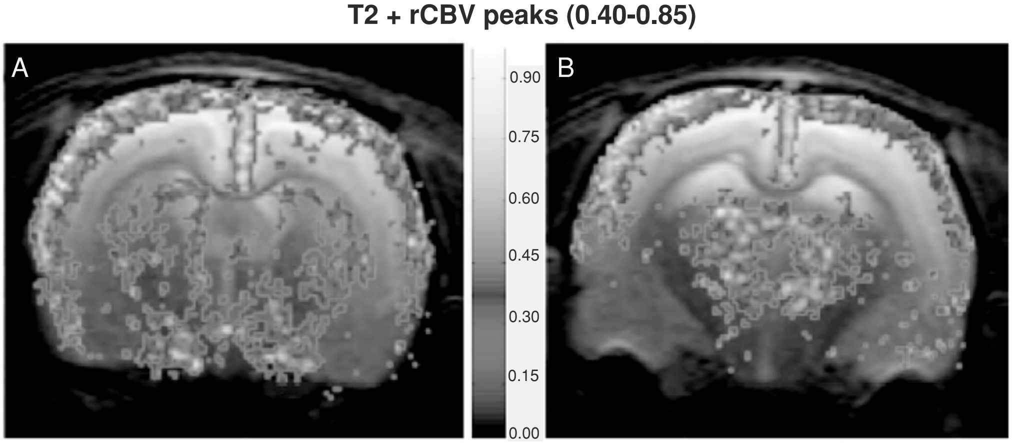

Fig. 3. Maps of CBV increase in an epileptic animal, generated to show the highest values of rCBV increase (cutoff at 0.40) at two different levels (A, 0.26 mm from bregma, B, −2.5 mm from bregma) superimposed to T2W images. In the cerebral cortex the simultaneous detection of the two signals shows clearly that rCBV peaked in the superficial layers, overlying the T2W hyperintensity. An increase of rCBV is also evident in the dorsolateral striatum and medial basal forebrain (A), as well as in the medial thalamus (B). In the hippocampus the rCBV increment, although significantly high was below the cutoff level adopted for the purpose of these maps. Reprinted with permission from Fabene *et al*. [138]. (See also Plate 67 on page XLVI in the Color Plate Section.)

which progressively normalizes by 5–9 days and finally increases in the chronic phase (3–9 weeks). The latter phase appears to coincide with the onset of spontaneous seizures [132,134]. It has been suggested that the progressive T_2-weighted hyperintensity in the piriform and entorhinal cortex may characterize the initial step leading to the development of epilepsy and late gliosis could result from spontaneous seizures [132]. Nairismagi *et al*. were unable to demonstrate a relationship between early MRI changes and subsequent severity of epilepsy and tissue damage. However Roch *et al*. indicated that P21 rats that had early T_2 increases did develop epilepsy, although only a subpopulation developed hippocampal sclerosis, an observation which remains as yet unexplained. One suggestion for the lack of correlation was the limited MRI spatial resolution. Some studies are now using high-resolution imaging in combination with other MRI techniques such as magnetization transfer (MT) contrast, which may provide the visual assessment of hippocampal formation, structure and damage necessary to investigate subtle morphological changes [135–137].

Functional Imaging in Epilepsy

During the last few years fMRI and CBV mapping have been used to investigate the underlying changes in neuronal activity and hemodynamics during and after seizure activity. Fabene *et al*. have demonstrated regional structural and functional MRI changes 12 h following onset of status. They concluded that T_2-weighted imaging hyperintensity changes in a cortex, hippocampus, amygdala, and medial thalamus are due to edematous alteration; regional increases in CBV, indicative of degenerating neurons, were not found in the areas of marked increase in T_2, suggesting that CBV may provide a mechanism to track progressive pathology (Figure 3) [138]. EEG has been used together with fMRI to identify areas of neuronal activity during seizures in rat models of absence epilepsy. Studies have shown that spontaneous spike-and-wave discharges, measured with EEG, are accompanied by transient focal increases in BOLD signals in regions which are characteristic of absence epilepsy [139,140]. It remains to be seen how these initial BOLD changes will compare with long-term histological changes, seizure frequency, and severity.

Neurodegenerative Disorders

Neurodegenerative disorders such as Alzheimers's disease (AD) or Parkinson's disease (PD) are devastating progressive illnesses. A combination of MRI approaches such as pharmacological MRI, DTI, and anatomical studies of brain atrophy has proved particularly useful in understanding the etiology and progression of these diseases [141–143].

Parkinson's Disease

This condition is characterized by the progressive loss of nigral neurons and striatal dopamine resulting in progressive loss of motor control and the characteristic symptoms of the disease. Experimental models of PD fall into three major categories. The first are pharmacological models, using for example reserpine or amphetamine administration to deplete dopamine, which are largely reversible treatments. The second group involves lesioning using neurotoxins, which is permanent. Thirdly, transgenic mouse models have been developed.

Imaging experimental models has long been in the domain of PET imaging with the availability of radioligands to monitor both pre- and postsynaptic function [144]. This methodology has now been largely supplanted by functional MRI to image brain activation patterns. BOLD fMRI showed bilateral overactivation in the sensorimotor cortex, suggesting that the mutual influence of the two hemispheres is important in the pathophysiology of PD [145] Another new approach is pharmacological MRI (a term used to describe drug induced functional MRI changes) where activity is induced by levodopa [146], D1 and D2 receptor agonists [147], amphetamine [148], or dopamine transporter agonists [149].

Using anatomical MRI sequences, temporal signal changes in T_1 and T_2 have been used to map regions of degeneration after lesioning in non-human primates [150] and attempts have been made to correlate T_1 relaxation times with the abnormal accumulation of iron in degenerating dopaminergic neurones in a neurotoxin rat model [151].

Alzheimer's Disease

Alzheimer's Disease is the most common dementia in Western societies. Pathohistological findings include widespread neuronal degeneration and β-amyloid (Aβ) plaques. AD models involve focal cerebral lesions that are mostly induced by neurotoxins, i.e. 6-OH dopamine. Furthermore a significant number of transgenic mouse models has been developed, which present different aspects of the disease such as over-expression of amyloid precursor protein (APP) and/or presenilin (PS) leading to amyloid plaque formation from the age of 6 months onward.

Anatomical MRI has been used to assess atrophy by measuring (partial) brain volumes or indirectly ventricular volumes [152]. Even before the onset of Aβ deposition, reduced hippocampal volume and corpus callosum length can be detected by MR microscopy [153]. DTI revealed significant differences between APP mice and control mice following the development of AD-like pathology, suggesting that primary or secondary white matter injury can be detected by DTI [154].

T_2 imaging showed a significant reduction of the relaxation time in the hippocampus, cingulate, and retrosplenial cortex, but not the corpus callosum of APP mice [155]. This relaxation contrast has been used to detect plaque-like structures in the cortex and hippocampus with high-resolution anatomical MRI [156]. Using angiography, flow voids were detected at the internal carotid and the large arteries at the circle of Willis in APP mice, suggesting that soluble Aβ may have deleterious effects on the vasculature [157]. The hemodynamic response to stimulus was shown to decrease with increasing age of the APP mice and with increasing stimulus amplitude as compared with wild-type animals, which can at least partially be explained by the deteriorating vasculature [143].

With the advent of molecular imaging several different contrast agents have been developed to label amyloid plaques. Some of these use magnetically labeled Aβ peptides; to get these agents to the target the blood–brain barrier needs to be opened [158]. Alternatively, a derivative of human Aβ peptide has been developed that is capable of crossing the intact blood–brain barrier and of selectively targeting individual amyloid plaques [159].

Huntington's Disease

Huntington's disease (HD) is an inherited neurodegenerative disease, in which there is progressive motor and cognitive deterioration, characterized by degeneration of GABAergic neurones localized mainly within the deep gray matter of the basal ganglia. Experimental models are based on acute lesioning using GABAergic antagonists or chronic lesioning using systemic administration of 3-nitroproprionic acid [160,161]. Since the discovery of the gene mutation for the disease, new transgenic mouse models are being developed [162]. Imaging data are largely PET-based, mapping regions of reduced metabolism indicative of cell loss [163]. Striatal lesions are visible with T_2-weighted and DWI protocols [164], although at acute time-points only DWI provides sufficient sensitivity [165]. DTI shows a significant decrease in relative anisotropy in the regions of corpus callosum, external capsule, and hippocampus in the 3-NP-treated rats [166]. A more extensive review of MRI and MRS in the 3-NP model can be found in a review by Lee and Chang [166].

CNS Inflammation

The inflammatory response is part of the hosts defense to injury and infection, but can exacerbate tissue injury when excessive or inappropriate. It has become clear that inflammation contributes not only to the archetypal CNS inflammatory disease, multiple sclerosis (MS), but also to a wide variety of acute neurological and chronic neurodegenerative diseases, such as stroke, head trauma, Alzheimer's disease, prion disease, and HIV-related dementia. Despite this, little is known of the effects of inflammatory processes within the CNS, or their contribution to MR images of human neuropathologies.

Multiple Sclerosis

Despite a wealth of studies, the pathogenesis of MS is still not fully understood. A primary goal of animal studies is to determine the relationship between the histopathology of a disease and the MRI characteristics. The most commonly used animal model is experimental allergic encephalopathy (EAE), an autoimmune CNS disorder that can be induced in susceptible species, such as mice, rats, guinea pigs, and non-human primates [167,168]. However, few of these models adequately represent all of the features of human MS, as the lesions evolve spontaneously at any site within the brain and often vary in temporal progressions. An alternative model is the delayed-type hypersensitivity (DTH) model in the rat [169], which involves sensitization of the immune system to a non-CNS antigen previously deposited in the brain. This model exhibits all the primary features of MS lesions: T-cell and macrophage infiltration, BBB breakdown, edema and tissue damage, and primary demyelination. A major advantage of this model for longitudinal MRI studies is that the site of the lesion is precisely dictated by the location of the intracerebral antigen injection.

MRI findings in the EAE models include increased T_2 and ADC values, corresponding broadly to those found most commonly in MS patients. However, only a relatively small number of studies have investigated correlations between MRI and histopathology obtained at the same time point. An increase in T_2 has been found to correspond to regions of macrophage recruitment and edema in both guinea pig [170] and rat EAE models [171]. However, T_2 changes were also associated with demyelination in the rat [171], but not in the guinea pig [170]. In the *C. jacchus* marmoset model of EAE increased proton density and T_2 appear to be associated with regions either of perivascular cuffing, demyelination, or perivascular gliosis [172]. The variability of these findings suggest that T_2-weighted MRI alone is not a reliable method of distinguishing purely inflammatory lesions from either demyelinating or remyelinating lesions [172,173].

In MS patients, areas that are enhanced following injection of an MRI contrast agent are generally considered to be a sensitive indicator for disease activity. In both guinea pig [174] and rat [175] models of EAE, BBB breakdown has been found to correlate with macrophage recruitment. In contrast, in the *C. jacchus* marmoset EAE model, which arguably provides the most accurate representation of the relapsing-remitting form of MS, contrast-enhancing areas correlated solely with acute, actively demyelinating lesions [173]. However, recent work in the rat DTH model [176] has demonstrated that axonal injury and inflammatory events occurring within a lesion are not restricted to the period of BBB breakdown and contrast enhancement. These findings suggest that MS disease progression may persist despite an intact BBB, and, consequently, contrast-enhancement may not be an accurate marker of disease activity. Recently, it has been suggested that a more appropriate method may be to monitor monocyte infiltration ("the major source of demyelination in EAE") via cells labeled with iron oxide particles which may be detected by MRI, thereby allowing assessment of the inflammatory activity induced by EAE [177].

Other imaging modalities have been used less frequently, but have yielded some interesting findings. It has been suggested that DTI may distinguish between acute and chronic EAE lesions [178], such that in acute lesions diffusion increases in all directions, probably as a consequence of edema, whilst in chronic lesions diffusion only increases perpendicular to the main axon axis, possibly reflecting demyelination. Recent measurements of magnetization transfer ratio (MTR) in EAE [179] have suggested that decreases in MTR, which are frequently assumed to reflect demyelination in human MS, may in fact result from inflammatory related changes to white matter structure rather than myelin loss *per se*. In contrast, the short component of tissue water T_2 may more accurately reflect myelin content [179].

New contrast agents have recently provided an alternative approach to imaging EAE. A recent study has shown that the use of a superparamagnetic iron oxide contrast agent enables macrophage recruitment to the CNS to be followed *in vivo*, because those particles are scavenged by macrophages [180]. Another study demonstrated that Gd-DTPA leakage clearly preceded monocyte infiltration as imaged by uptake of ultra small particles of iron oxide (USPIO), which was maximal only during full-blown EAE [181]. Similar particles have been used to track the migration of labeled T-cells into the central nervous system in EAE [182]. Rausch *et al.* showed that significant changes of MTRs of up to 35% were observed in areas of USPIO accumulation. However, the areas of monocyte infiltration only coincided in part with areas of BBB breakdown, suggesting that infiltrating monocytes are related to demyelination in EAE, but not the breakdown of the BBB (Figure 4) [183]. Future contrast agent research may concentrate on detection of inflammation before the onset of clinical symptoms, e.g. by specific contrast agents that target early inflammation markers like E-selectin [184] or superparamagnetic antibodies specific for cell surface markers of CD4+ T-cells, CD8+ T-cells, and Mac1+ cells of EAE and TMEV mice [185].

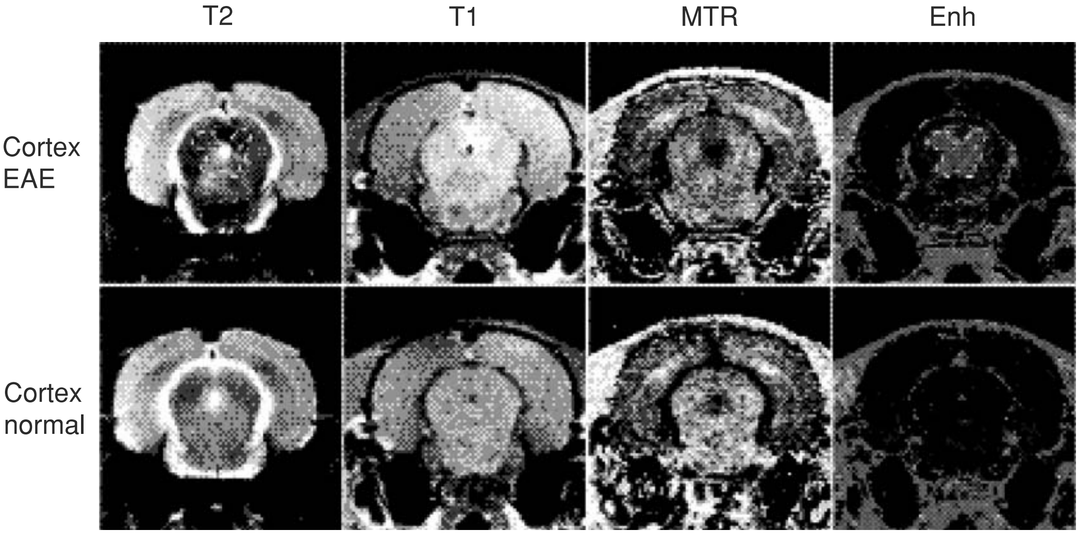

Fig. 4. Visualization of demyelination using USPIO particles in the EAE model of MS. The T_2 and precontrast T_1 images display hypo- and hyperintense areas, respectively, induced by accumulation of USPIO. The spatial localization and extent of the USPIO are the same in both images; however, the contrast is stronger in the T_2-weighted scans. MTR maps display no clear signs of MTR reduction. Enhancement of Gd-DOTA is visible in structures of the midbrain. The discrepancy between the spatial localization of the USPIO and the Gd-DOTA enhancement is demonstrated by dotted lines and dashed lines. The area marked by the dotted line accumulated USPIO but no Gd-DOTA. The reverse situation can be observed in the area marked by the dashed line. Reprinted with permission from Rausch *et al*. [183]. (See also Plate 68 on page XLVI in the Color Plate Section.)

Traumatic Brain Injury

Traumatic brain injury (TBI) results in a complex, heterogeneous pathology that varies considerably in both spatial and temporal dimensions depending on the severity of the insult and the location of the initial impact. A number of experimental models have been developed to simulate brain trauma; the most commonly used are weight-drop [186], impact acceleration [187], fluid percussion (FP) [188,189], and cortical contusion injury (CCI) [190] (for a review of these models see Gennarelli *et al*. [191] and Lighthall *et al*. [192]). Each model is designed to closely simulate specific components of the clinical pathology, which means that no single model is necessarily the best. Although the nature of the physical force differs between the models, the resulting acute and chronic destruction of gross tissue elements is somewhat similar and can be varied by adjusting the physical force used to produce the injury.

Autoradiography has been the most widely used imaging modality for TBI research, although there is an ever increasing number of publications using MRI as the primary imaging modality. Autoradiography is generally used for mapping CBF or cerebral metabolic rate of glucose utilization, but it has also been used to determine calcium accumulation [193] and microglial/macrophage activation or infiltration [194] after injury. Time-course analysis after CCI injury details a unilateral drop in CBF lasting for days post-injury [195] with a concomitant hyper- and subsequent hypo-metabolic state as determined by CMRG measurements [196]. Recent advances in PET scanner technology [197] have enabled non-invasive studies of metabolism to sequentially image the same rat following head-trauma [198]. It is likely that this methodology is set to be exploited much further for TBI research in the coming years with the increasing availability of new tracers to map different receptor distributions and gene expression [197].

The continual development of MRI techniques to assess pathophysiology is particularly advantageous in TBI research, since the high spatial and temporal resolution that is now routinely achieved with MRI is particularly useful given the highly heterogenous nature of this condition. T_1, T_2, and DWI sequences have been employed to monitor contusion volume in rats [199–203] and mice [204], identify necrotic from edematous brain tissue [205], track brain anatomy at various developmental ages and times after injury [206,207], and to compare different TBI models [208]. A model has also been proposed to map brain water content based on the signal contrast in T_1-weighted images [209], although this methodology has yet to gain wide acceptance by the MR community.

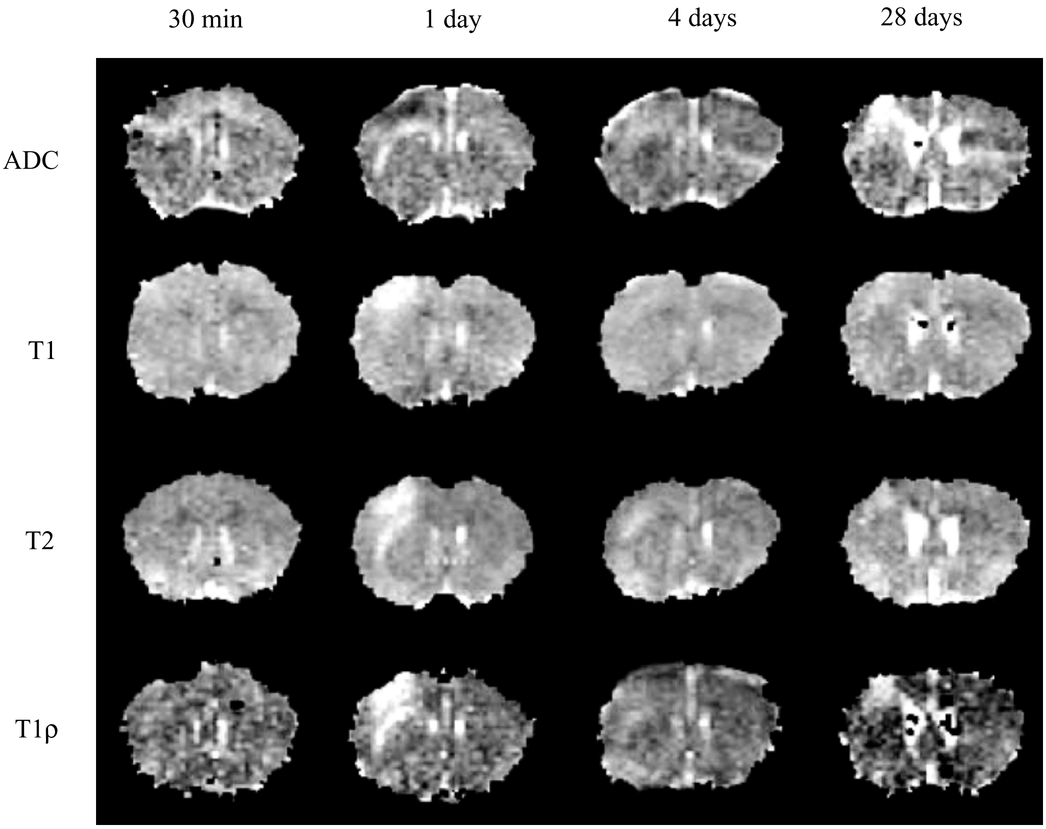

Fig. 5. Multi-parametric (ADC, T1, T2, TIρ) multi-time-point MRI datasets were acquired after traumatic brain injury using the cortical contusion rat model. Injury was produced using a pneumatic piston (2.5 mm ϕ), which was advanced onto the dura at 4 m s^{-1} through as 5-mm craniotomy and to a depth of 2 mm over the left parietal cortex. ADC values were decreased at 30 minutes and 1 day after which they pseudo-normalised and subsequently increased by day 4. Core T1, T2, and T1 ρ were all increased at all times post-injury.

The high sensitivity afforded by diffusion imaging has been used to detect very early decreases in the ADC indicating cytotoxic edema followed by a later increase indicative of a vasogenic component [210–215]. Not all groups have documented this initial ADC decrease [216–218] and this may be related to the model used, the injury severity or most likely to the placement of the measurement region-of-interest. Further work investigating mechanisms of diffusion change has suggested that in the case of a stab injury, ADC changes observed in areas remote from the initial injury site may reflect alterations in extracellular matrix composition [219].

Sub-dural hemorrhage that is present immediately after contusion injury is highly visible on T_2* images due to the magnetic susceptibility differences relative to the surrounding tissue, although this resolves with time [215]. While this susceptibility effect results in distortion of echo-planar spin echo images, it will certainly produce large areas of signal dropout for gradient echo image acquisition, as typically used for fMRI studies. Thus, early time-point functional investigations may be limited to PET or autoradiographic studies.

Contrast-enhanced imaging has been used to map regions of increased blood–brain barrier permeability [220–222], together with the deleterious effects of secondary injury [223] and initial decreases in CBV [213] following injury. However, the use of contrast agents for quantifying either blood volume or perfusion in regions where the BBB is permeable is inacurate, and this may be reflected in this latter study that showed CBV maps that were not well correlated with histological damage, together with large inter- and intra-subject variability. Using continuous arterial spin-labeling (CASL) to map CBF circumvents this problem [224]. Early reductions in CBF have been reported after CCI using CASL [215,225,226] together with loss of vascular reactivity [225]. Monitoring CBF at different times after injury in the same rat using this technique demonstrated hypoperfusion in core and contusion boundary regions followed by a return to normal values at the chronic stage [215,227]. These findings are in good agreement with autoradiographic data [195].

Diffuse axonal injury, a hallmark of TBI, is considered to be an important determinant of functional outcome. MT imaging has been shown to be sensitive to axonal injury in a number of disease states. The MTR is significantly decreased in regions of axonal injury after rotational acceleration injury in the pig [228,229] and in core regions after contusion injury in the rat [215]. The agreement between MTR abnormalities and axonal pathology assessed by histology was good, and MT is reported to be highly sensitive for detecting relatively mild injury [229], but future studies may be limited to large animals, since the rat exhibits a much lower white/gray matter ratio, making detection of white matter pathology difficult.

More recently, MRI has been used to assess development of interventional pharmacological strategies for use in TBI. Using capsaicin-induced neuropeptide depletion to examine the role of neurogenic inflammation, Nimmo *et al*. demonstrated reduction in post-traumatic edema formation (DWI), BBB permeability, free magnesium decline, and motor and cognitive deficits, concluding that neurogenic inflammation may play an integral role in the development of edema and functional deficits following TBI [230].

Conclusion

The combination of appropriate imaging techniques and suitable animal models of disease can greatly expand our understanding of human brain pathologies. This experimental imaging partnership has contributed to the development of novel imaging techniques, to the promotion of better diagnostic and prognostic measures, and to the elucidation of basic mechanisms of cellular injury leading to improved therapies.

MRI is expected to play an increasingly important role in future research, especially in areas where its noninvasive character is a significant advantage, such as the phenotyping of transgenic animals and longitudinal trials of drug therapies.

Acknowledgments

The authors would like to thank Dr. N.R. Sibson and Dr. N.G. Harris for their contribution to the manuscript. We acknowledge the Wellcome Trust and the BBSRC for their support of the work carried out at Radiology and Physics Unit of the Institute of Child Health, Great Ormond Street Hospital and the Wellcome Trust High Field MR Research Laboratory.

Introduction

Magnetic resonance spectroscopy (MRS) has the unique ability to measure the chemical content of living tissue in the body, repeatedly and noninvasively. This permits investigations of biology and physiology in human and in animal models *in vivo,* in both healthy and diseased tissues. From such studies, information on tumor diagnosis and response to therapy, as well as prognostic information, has been obtained. MRS can also be used for *in vitro* studies of cell and tumor extracts. Now with high-resolution magic-angle spinning (HR-MAS) spectroscopy, small pieces of intact tissue (e.g. biopsies) can also be examined.

The first *in vivo* ^{31}Phosphorus (^{31}P) MRS study carried out in an animal tumor model was performed in 1981 [1], followed a couple of years later by the first *in vivo* human tumor study [2]. The noninvasiveness of MRS makes it an important tool to study cancer *in vivo*, where serial measurements can be made on the same animal. MRS, using different nuclei including ^{1}H, ^{31}P, ^{19}F, and ^{13}C, has been used widely to study the biology and therapy of cancers in cultured cells and in animal models [3–11].

Using ^{31}P MRS, markers for tissue bioenergetics [nucleotide triphosphate (NTP), inorganic phosphate (Pi)], intracellular pH (pHi), and membrane turnover [phosphorus-containing components of phospholipid membrane: phosphomonoester (PME) and phosphodiester (PDE)] can be readily observed (Figure 1).

PMEs comprise phosphocholine (PC) and phosphoethanolamine (PE), and PDEs glycero-phosphocholine (GPC) and glycero-phosphoethanolamine (GPE) as shown by *in vitro* ^{31}P MRS of cancer cells or tumor extracts (Figure 2), where these metabolites are more readily resolved than *in vivo*.

^{1}H and ^{13}C MRS can also provide information on tumor metabolism *in vivo.* Metabolites, such as lactate, lipids, and choline-containing compounds, can be observed in ^{1}H MRS [12]. ^{13}C-enriched substrates (e.g. glucose) and ^{13}C MRS can be used to study metabolic pathways (e.g. glucose metabolism) of tumors [13]. *In vivo* ^{19}F, ^{1}H and ^{13}C MRS have been used to monitor the metabolism of drugs containing those nuclei *in situ* [8–10, 14, 15].

Many more metabolites can be observed by HR-MAS (Figure 3) in comparison to *in vivo* MRS because HR-MAS gives better-resolved spectra. This methodology has the advantage that pieces of intact tissue can be examined with minimal sample preparation and sample destruction but there is still a risk of sample degradation during the examination. Far superior spectral resolution to either HR-MAS or *in vivo* MRS is obtained from *in vitro* MRS of extracts of cells or tissue (Figure 4); however, tissue extraction is destructive, has longer sample preparation time, and samples will certainly be altered during the extraction procedure (but mostly in well-understood ways). Despite the poorer spectral resolution, the main advantage of *in vivo* MRS is that biochemical and functional information can be obtained noninvasively in the living tissue, whereas biopsy samples required for HR-MAS and *in vitro* MRS are already a step away from the *in vivo* situation.

This chapter will present some examples to illustrate the application of various MRS methodologies in preclinical models to study tumor biology and therapies. The headings represent the major areas that have been studied and reported in the literature.

Tumor Biology and Physiology

Tumor Hypoxia

Hypoxia is a reduction in the normal level of tissue oxygen tension (pO_2), which is very common in cancer. This is due to rapid cell growth and chaotic and leaky immature blood vessels associated with tumors. Hypoxia is of major interest in the oncology field, as tumor cells that are exposed to hypoxia can become resistant to radiotherapy and chemotherapy and then the surviving cells can lead to tumor re-growth and metastasis [19]. ^{31}P MRS is a valuable tool for studying hypoxia since tumor metabolites, such as NTP, PCr, and Pi, reflect tumor bioenergetics. Many studies have shown that progressive tumor growth and insufficient blood flow result in a more acidic pH and a decrease in high energy phosphate metabolites, such as NTP and PCr with a concomitant increase in Pi [20–23].

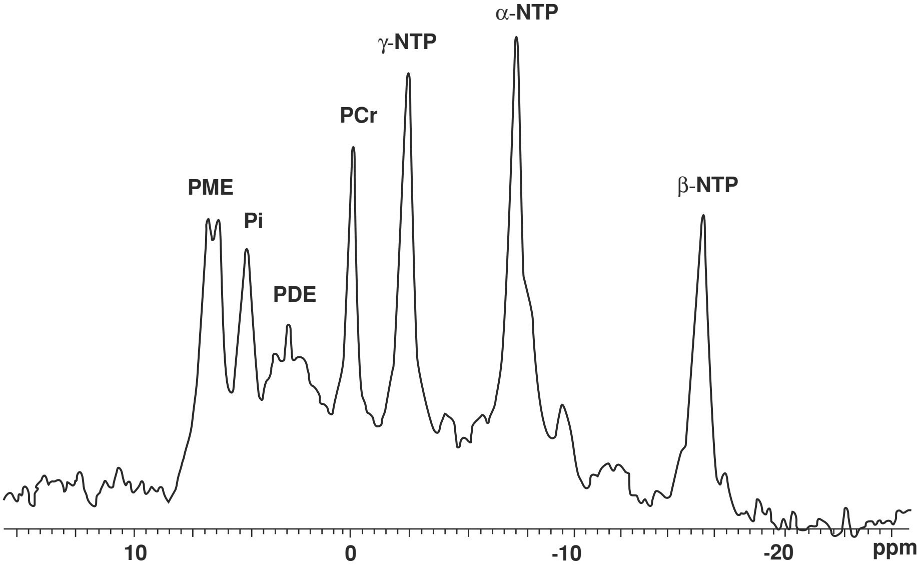

Fig. 1. *In vivo* localized ^{31}P MRS of an HT29 tumor. Peak assignments were phosphomonoester (PME), phosphodiester (PDE), inorganic phosphate (Pi), phosphocreatine (PCr), and nucleotide triphosphate (α-, β-, γ-NTP).

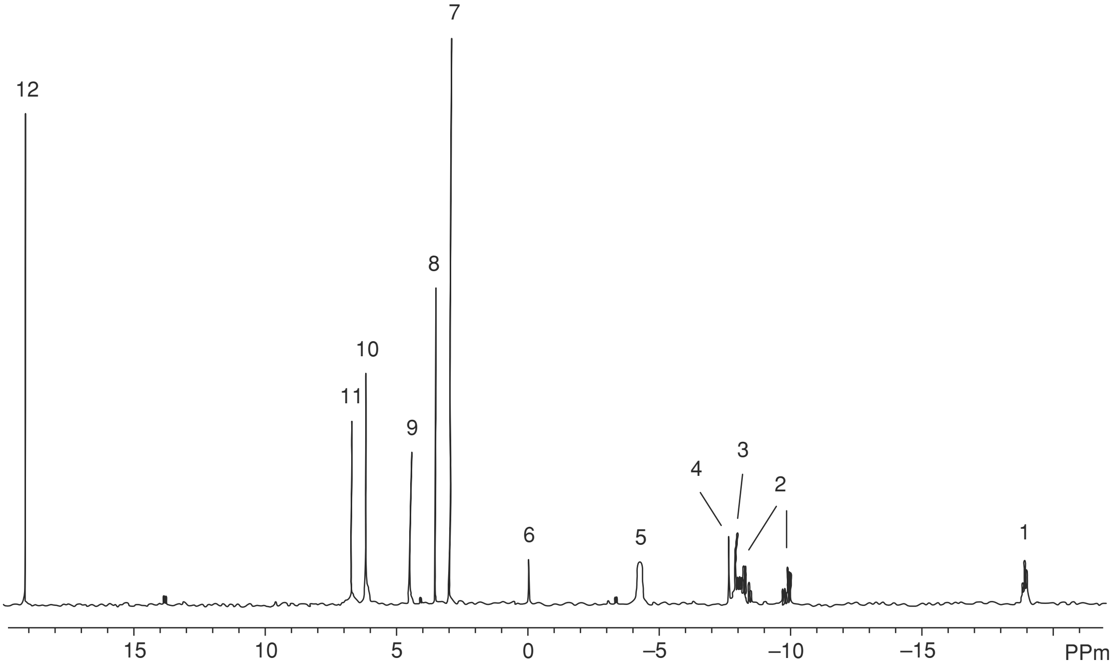

Fig. 2. *In vitro* ^{31}P MRS of a perchloric acid extract of an HT29 tumor. Peak assignments were β-nucleotide triphosphate (1), uridine diphosphate sugars (2), α-nucleotide triphosphate (3), α-nucleotide diphosphate (4), γ-nucleotide triphosphate + β-nucleotide diphosphate (5), phosphocreatine (6), glycero-phosphocholine (7), glycero-phosphoethanolamine (8), inorganic phosphate (9), phosphocholine (10), phosphoethanolamine (11), and methylene diphosphoric acid (12—included as a reference for chemical shift and quantitation).

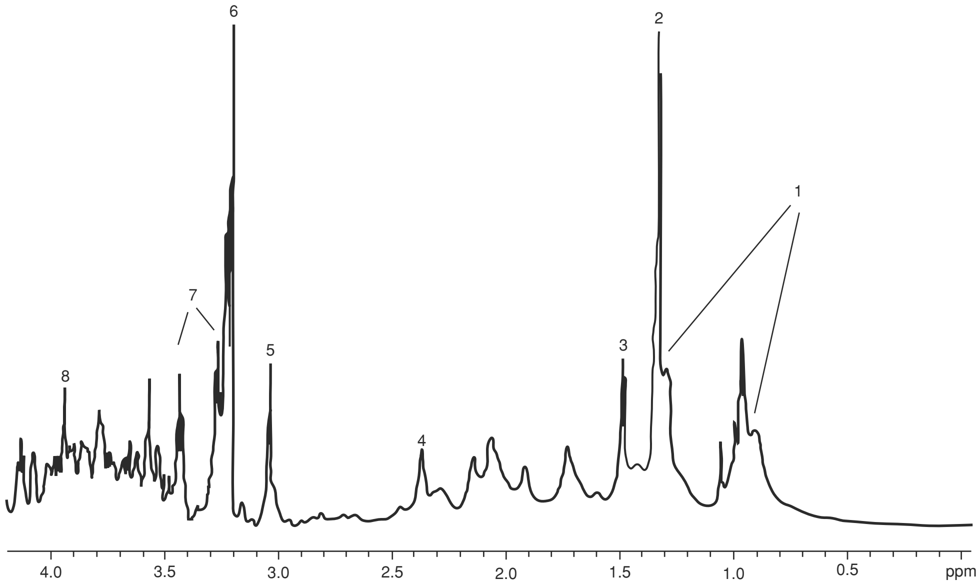

Fig. 3. HR-MAS ^{1}H spectrum of an HT29 tumor. Peaks assigned as lipids (1), lactate (2), alanine (3), glutamate (4), creatine + phosphocreatine (5), choline-containing compounds (6), taurine (7), and creatine + phosphocreatine (8). For detailed peak assignments, see references [16,17].

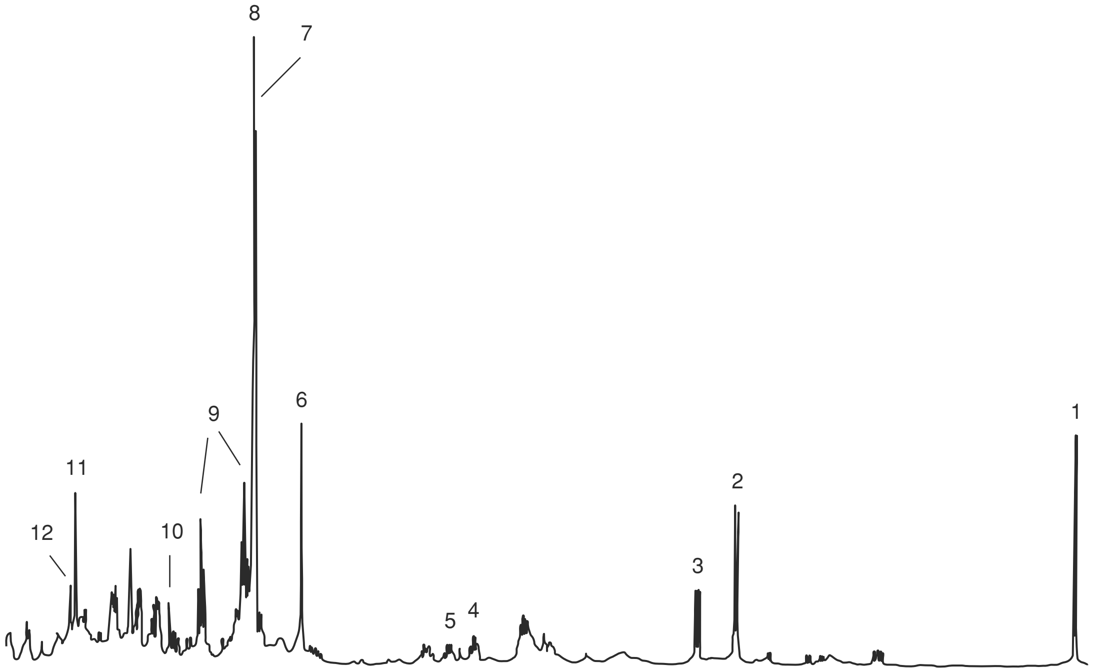

Fig. 4. *In vitro* ^{1}H MR spectrum of an HT29 tumor extract. Peaks assigned as sodium 3-trimethyl-silyl-2,2,3,3-tetradeuteropropionate (1—included as a chemical shift reference and for quantitation), lactate (2), alanine (3), glutamate (4), glutamine (5), creatine + phosphocreatine (6), phosphocholine (7), glycero-phosphocholine (8), taurine (9), glycine (10), creatine (11), and phosphocreatine (12). For detailed peak assignments, see references [16,18].

In vivo ^{19}F MRS, together with endogenous probes, can also be used to study hypoxia and oxygenation in tumors. Hypoxia can be measured by using a fluorinated hypoxia-imaging agent, for example SR4554 or other fluorinated 2-nitroimidazoles [24–25]. Oxygenation may be measured using organofluorine compounds such as perfluorocarbons, which have a very high affinity for oxygen [25–27].

Glycolytic Metabolism in Tumors

It has been known since Warburg's time that tumor cells synthesize high levels of lactate through glycolysis [28]. Most tumors *in vivo* synthesize some ATP by oxidative metabolism, and some by glycolytic metabolism to lactate (aerobic glycolysis). If the oxygen supply is suddenly decreased (acute hypoxia), the tumor cells switch to anaerobic glycolysis. Many tumors have high rates of glycolysis regardless of their oxygen supply and the rate of glycolysis appears to be associated with the differentiation status and growth rate of the tumor [29,30]. This increased rate of glycolysis could be caused by the upregulation of hypoxia inducible factor-1 (HIF-1), overexpressed in many cancers [31] both constitutively [32] and as the result of hypoxia [19]. HIF-1 is a transcription factor that can bind to hypoxia response elements and activate gene transcription. It has been implicated in, for example, the regulation of angiogenesis, glucose transport, glucose metabolism, and nitric oxide metabolism [33].

^{1}H MRS can be used in studies of tumor glycolytic metabolism noninvasively, as a multiple-quantum-coherence-edited sequence allows the measurement of lactate [34]. ^{13}C-enriched substrates, together with ^{13}C MRS methodologies, can also be used to study the *in vivo* rates of glycolysis in different tumor types [13,35].

Tumor pH

Many cellular processes depend on pH, including synthesis of macromolecules, cell proliferation, DNA synthesis, the activity of various enzymes (such as enzymes of glycolysis), and the transport of metabolites and drugs [36]. Hence, tumor pH plays an important role in tumor transformation and growth, as well as treatment [29]. Tumor cells were found to have a lower extracellular pH (pHe) than normal cells, whereas the intracellular pH (pHi) is relatively high (about 7.0–7.2) [37]. Low pHe has been associated with tumorogenic transformation, chromosomal re-arrangements, extracellular matrix breakdown, migration and invasion etc [38]. High pHi provides tumor cells with a growth advantage over normal cells [39]. This is an intrinsic feature of the tumor metabolic phenotype and it is caused by alterations either in acid export from the tumor cells or in clearance of extracellular acid. Tumor pH gradients have practical importance because most anti-cancer drugs must be transported by either active transporters or by passive diffusion into cells, where they frequently undergo further metabolism. As all these processes might be pH sensitive, the cytotoxic activity of an anti-cancer drug could depend on both pHi and pHe [29,40].

Therefore, measuring tumor pH could provide insights into tumor metabolism and its response to certain therapies [41–43]. ^{31}P MRS offers the unique opportunity to measure intracellular pH (pHi) in the tumor noninvasively; it is calculated from the chemical shift (i.e. frequency) between the Pi resonance (pH sensitive) and the pH insensitive metabolite, such as PCr or NTP. Tumor pHe can be measured by introducing an endogenous pH probe, such as ZK150471 and 3-APP, into the animal which may be assessed by *in vivo* ^{19}F or ^{31}P MRS, respectively [44,45].

Phospholipid Metabolism in Tumors

Phospholipid components have established roles both as structural building blocks of cell membrane and as regulators of cell function. Choline signals have generally proved to be the most diagnostically and prognostically useful elements of ^{1}H MRS of tumors. Elevated levels of choline-containing compounds in cancer were found to be associated with tumor growth and cell proliferation and have been used as endogenous biomarkers of cancer [46–48]. ^{1}H MRS detection of the total choline level in patients allowed distinction between malignant and benign breast lesions [49]. Assessment of phospholipid metabolism may also provide insights into tumor response following treatment.

In vivo ^{1}H and ^{31}P MRS are ideally suited to measure phospholipid metabolites as high levels of phospholipid metabolites are present in tumors and cancer cells. *In vivo* ^{1}H MRS will provide information on total choline level (which includes free choline, PE, PC, GPC, and GPE) (Figure 5), whereas PME and PDE resonances are found in *in vivo* ^{31}P MR spectra [11,50] (Figure 1).

Combined MR and chromatographic analysis of aqueous extracts of rat tumors has unequivocally demonstrated that the PME signal in *in vivo* ^{31}P MR spectra mainly comprises phospholipid metabolites, PE, and PC, rather than sugar phosphates [50] and can sometimes be resolved *in vivo* by ^{31}P MRS [51,52]. An increase in PME has been associated with membrane during rapid tissue growth [11]. On the other hand, the PDE resonance comprises GPC and GPE [50] which are associated with membrane breakdown.

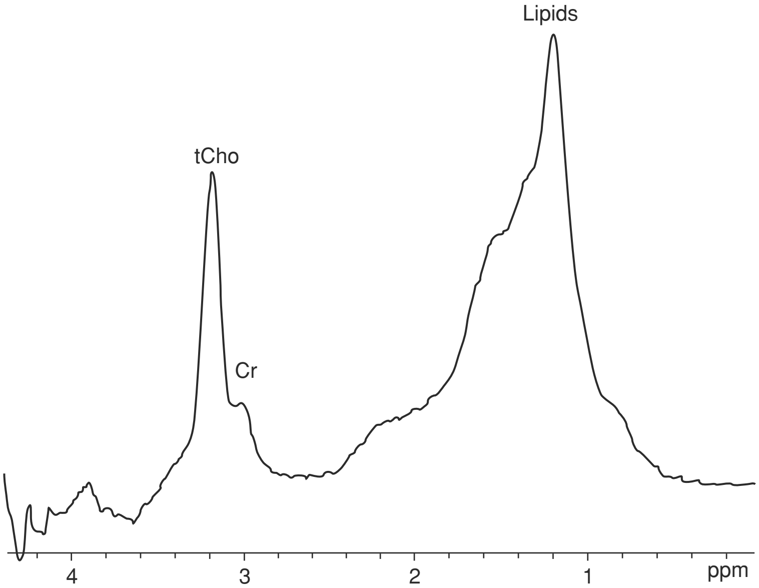

Fig. 5. *In vivo* localized ^{1}H MR spectrum of an HT29 tumor in a mouse. Peak assignments are total choline (tCho), creatine (Cr), and total lipids (Lipids).

Lipid Metabolism in Tumors

High levels of MR-detectable lipids (intracellular lipid vesicles from the cytosol) are present both in proliferating and malignant cells in a variety of tumors [53–55] (Figure 5). These lipids are readily detected by ^{1}H MRS and resonate at 1.3 ppm (the signal from the $CH_2CH_2CH_2$ group). The underlying reason for this high level of lipid remains unclear. In *in vitro* cell culture studies, it was found that apoptosis was associated with the accumulation of the $CH_2CH_2CH_2$ lipid groups, whereas in necrosis there was no change in MR-detectable lipids [56,57]. However, in solid tumors the presence of this lipid resonance was found to coincide with areas of necrosis [55,58,59].

Recently, Griffin *et al*. [60] have used *in vivo* and *in vitro* ^{1}H MRS and HR-MAS to study a rat BT4C glioma model. A strong ^{1}H MRS lipid peak was detected during tumor growth and polyunsaturated fatty acid was found to accumulate following apoptosis after ganciclovir-thymidine kinase gene therapy. No sign of necrosis was found by histological or immunohistochemical assays in tumor tissue during treatment. Taking together the MR and histology findings, the data suggest that the accumulation and alterations in the degree of lipid saturation occur in the ^{1}H MRS visible lipids during apoptosis and that these lipids arise from cell constituent breakdown products forming lipid vesicles in dying cells [60,61].

Oncogene Function

Genomic and proteomic information is transforming all fields of cancer research. The increased understanding of the genomics and molecular pathology of cancer also provides a framework for designing new therapeutic strategies. The majority of the genes in most genomes is still of unknown function, and many studies on proteomics are attempting to fill this need. However, since information flows from DNA to RNA to protein to function, the role of each gene product in metabolism also needs to be studied to provide the link between the genotype and the phenotype [62]; a single gene mutation may cause alterations of metabolite levels of seemingly unrelated biochemical pathways and this is likely to happen when genes are constitutively overexpressed or anti-sense inhibited.

MRS could be a very useful tool for investigating specific oncogene function by using genetically modified tumor models with specific genes overexpressed or knocked down-regulated/knockedout. MRS can provide functional information on the role of these genes. Below are two examples where this type of methodology has been used to elucidate gene functions.

Hypoxia Inducible Factor-1

Cells have a highly efficient system for upregulating a host of genes that can counteract the effects of hypoxia.

Table 1: *In vitro* ^{1}H NMR measurement of metabolites in wild-type (Hepa WT) and HIF-1β deficient (Hepa c4) tumor extracts ($n = 4$)

Metabolites	Hepa WT	Hepa c4
Betaine	1.10 ± 0.20	0.40 ± 0.06*
Phosphocholine	3.78 ± 0.65	1.22 ± 0.24*
Free choline	0.43 ± 0.08	0.17 ± 0.02*
Glycine	3.93 ± 0.65	1.90 ± 0.38*
Taurine	16.10 ± 3.60	11.90 ± 1.61
Glycero-phosphocholine	2.58 ± 0.49	1.55 ± 0.24

*For Hepa WT compared to Hepa c4, $p < 0.05$. Values expressed as μmol/g wet weight.

Cellular responses to hypoxia include increased glycolysis and glucose metabolism, brought about by upregulation of transcription factors such as HIF-1. The HIF-1 transcription factor has been shown to be overexpressed across a broad range of cancers [31]. HIF-1α combines with HIF-1β to form a heterodimeric transcription factor that regulates the expression of glucose transporters and many of the glycolytic enzymes in cells, both constitutively and through cellular responses to hypoxia [63,64].

In HIF-1β deficient cells, a functional HIF-1 complex is unable to form and therefore unable to upregulate glycolysis [65]. Tumors grown from these HIF-1β deficient cells were studied using *in vivo* ^{31}P MRS and *in vitro* ^{1}H MRS. Tumors deficient in HIF-1β were found to have only 20% of the ATP content found in wild-type tumors suggesting that the absence of upregulated glycolysis prevents formation of precursors for anabolic pathways (Table 1), in particular synthesis of the purine rings for ATP [66].

This study has shown that the combined use of both *in vivo* and *in vitro* MRS can provide a powerful tool to measure physiological and biochemical parameters in control and mutant tumors.

Choline Kinase

Choline kinase (ChoK) is a cytosolic enzyme that catalyses the phosphorylation of choline to form PC which is involved in cell membrane synthesis. Elevated levels of PC and ChoK found in tumors are associated with cell proliferation and malignant transformation [46–49]. Correlation between increased ChoK activity and high tumor grade was reported indicating that increased ChoK expression and/or activity may cause increased PC and total choline levels [46,48,67,68].

To confirm this observation, Glunde *et al*. have studied the function of ChoK by examining a breast cancer cell line with knockdown of ChoK using small interfering RNA (siRNA) technology. ^{1}H MRS of cell extracts showed that the ChoK deficient cells have lowered levels of PC and total choline relative to empty vector controls [69]. Similar results were also observed in cells and xenografts treated with a ChoK inhibitor [70,71].

Therapy

MRS has much to offer for monitoring anti-cancer drugs, both in patients and in animal models. It can provide important insights into novel anti-cancer drug development, which could accelerate the drug development process. MRS can be used to determine whether adequate or optimal exposures of active agents are being achieved in the tumor [by measuring the drug itself as a pharmacokinetic (PK) marker] and/or whether the desired biological effect is being obtained [measuring pharmacodynamic (PD) markers e.g. choline].

Pharmacokinetic Markers

MRS has the unique ability, in some cases, to monitor the changing concentration of the anti-cancer drug itself as well as its metabolism and detoxification noninvasively in the tissue. *In vivo* ^{19}F MRS has been used extensively as an investigative tool for 5-fluorouracil (5-FU) pharmacology, a widely used cytotoxic drug in the clinic. It has been used to study the distribution and metabolism of this drug in normal and tumor tissues both in xenografts and in patients and has provided significant information on the fate and the potential PD effects of the drug [8,9,72]. The first *in vivo* ^{19}F MRS studies [73] were used to monitor the PK of 5-FU in rat tumors. Apart from the parent 5-FU, the ^{19}F MR spectra also showed 5-FU activated to cytotoxic fluoronucleotides and the appearance of detoxification products from the liver. There have been many other animal studies (and some human studies) on 5-FU and its derivatives [8,9,72].

MRS studies using other nuclei to monitor anti-cancer drugs have also been performed on tumors *in vivo*. ^{1}H MRS has been used to monitor iproplatin [14], ^{2}H MRS to monitor misonidazole [74], ^{13}C MRS to monitor temozolomide [15], ^{31}P MRS to monitor ifosfamide [75], and ^{195}Pt MRS to monitor carboplatin [76].

It would be very useful to have non-invasive predictive markers for response to chemotherapeutic drugs. Such a marker will minimize the patients' unnecessary exposure to cytotoxic drugs and clinicians could opt for an alternative or combination therapy at an earlier time if the patient is found to be unlikely to respond to certain treatments.

A PK study by ^{19}F MRS was performed recently on the oral anti-cancer drug capecitabine, a prodrug of 5-FU.

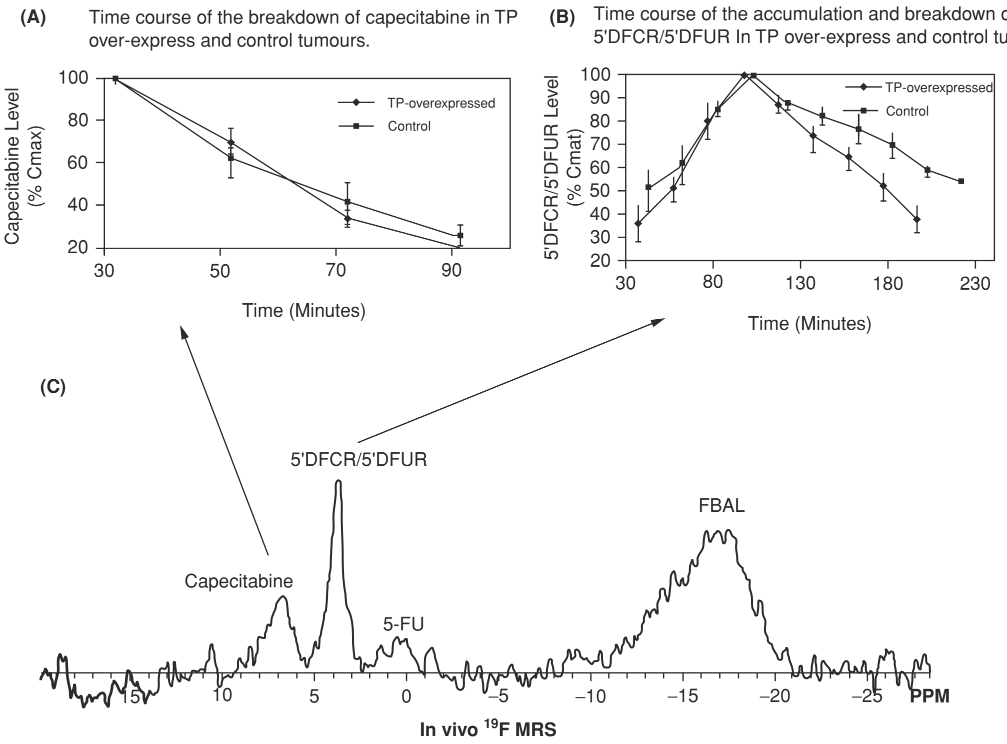

Fig. 6. (A) Time course of the breakdown of capecitabine. (B) Time course of the accumulation and breakdown of 5′DFCR/5′DFUR. (C) *In vivo* ^{19}F MR spectra of a tumor 52–72 min after an injection of capecitabine.5′-deoxy-5-fluorocytidine (5′DFCR); 5′-deoxy-5-fluorouridine (5′DFUR); 5-fluorouracil (5-FU); and α-fluoro-β-alanine (FBAL).

The final activation step in the tumor is from 5′deoxy-5-fluorouridine (5′DFUR) to 5-FU, catalyzed by thymidine phosphorylase (TP). Previous studies have shown that tumor response is strongly correlated with tumor TP; however, the methodologies for determining TP levels involve obtaining invasive biopsies from patients. A non-invasive PK marker for monitoring the uptake and breakdown of capecitabine and potentially for predicting treatment response would be a more desirable end point for use in clinical trials and eventually in the clinic.

The PK of capecitabine was monitored in 2T10 human bladder tumors engineered to overexpress TP, compared with wild-type and empty vector controls [77]. *In vivo* ^{19}F spectra were acquired after a single dose of capecitabine. In the TP-overexpressing 2T10 tumors, the rate constant of the breakdown of the intermediate molecules (5′DFCR + 5′DFUR) was doubled compared with controls (Figure 6). This study confirmed that the rate of 5′DFUR conversion is related to TP expression. ^{19}F MRS measurement of the PKs of capecitabine and its intermediate metabolites could be a non-invasive surrogate for measuring TP levels in patients and predicting response to capecitabine. A recent using 1.5T and 3T clinical systems *in vivo* ^{19}F MRS study [78] has detected capecitabine, as well as its metabolites and catabolites, in livers of patients with colorectal cancer.

Pharmacodynamic Markers

MRS also has much to offer for monitoring tumor response to anti-cancer drugs, both in patients and in experimental animals. Most of the published work has been performed on routinely used chemotherapeutic drugs but MRS can also offer important insights into novel anti-cancer agents in order to accelerate the drug development process. As many of the novel anti-cancer agents currently under development will not cause tumor shrinkage when used as single agents in Phase 1 clinical trials, MRS may have a role in monitoring their PD actions.

The following section demonstrates the use of *in vivo* and *in vitro* ^{1}H and ^{31}P MRS to assess tumor response to conventional cytotoxic and novel drug therapies that target specific molecular targets. The application of these MR methodologies may have potential to provide surrogate PD markers for use in clinic trials.

Conventional Cytotoxic Drugs

5-FU is a widely used cytotoxic drug in medical oncology. Street *et al*. [79] used *in vivo* and *in vitro* ^{31}P MRS to examine the PD effect of 5-FU on a mouse mammary carcinoma model. An increase in NTP/Pi and PCr/Pi ratios was observed *in vivo* 48 h after 5-FU treatment. The PE-to-PC ratio was also elevated relative to controls and this was found to be due to an increase in PE (as confirmed by *in vitro* ^{31}P MRS). In addition, increases in GPC and GPE were also observed [79].

Cyclin-dependent kinase Inhibitor

CYC202 (R-roscovitine, Cyclacel Ltd, Dundee, Scotland) inhibits the cyclin-dependent kinases 1, 2, and 7 and thus blocks cell cycle progression. Its action *in vivo* was monitored by ^{31}P MRS in human colon xenografts to gain insights into the biochemical changes associated with cell cycle disruption and to determine whether ^{31}P MRS could eventually be used as a surrogate marker of response in a clinical trial. CYC202 treatment for 4 days caused reduction in tumor proliferation and tissue pH and impairment in tumor bioenergetics [80]. If CYC202 comes to clinical trial, these ^{31}P MRS effects may provide a non-invasive surrogate marker for assessing tumor response in patients.

HSP90 Inhibitor

The heat-shock protein HSP90 is of interest as an anticancer target [81] because it helps maintain the shape of many oncogenic proteins; inhibiting single oncogenes with “magic bullet” drugs has proved somewhat disappointing as the cancers often become resistant. The HSP90 inhibitor 17-Allylamino, 17-demethoxygeldanamycin (17AAG) is currently under trial as an anticancer agent, and a surrogate marker of tumor response was needed for the clinical trial. The actions of 17AAG were monitored on several cultured human colon cancer cell lines and on a human colon tumor xenograft model [82]. Treatment with an inactive analogue, and an active analogue, 17AG, was also tried. In all cell lines, there were significant increases in PC and GPC. *In vivo,* after 4 days of 17AAG treatment, the tumors showed significant growth delay as well as increased ratios of PME/PDE, PME/total phosphorus (TotP), and PME/β-NTP and a decrease in the β-NTP/TotP ratio. A significant inverse correlation was found between the percentage of change in PME/PDE ratio and the percentage of change in tumor size following 17AAG treatment [82]. These ^{31}P MRS changes suggested that it would be possible to monitor tumors in patients during the Phase 1 clinical trials of 17AAG and such a study is currently under way.

Conclusion

There are many areas of cancer research including drug development studies where MR techniques can give important information both *in vivo* and *in vitro.*

Experimental Cardiovascular MR in Small Animals

Jürgen E. Schneider and Stefan Neubauer
Department of Cardiovascular Medicine, University of Oxford, John Radcliffe Hospital, Headley Way, Oxford OX3 9DU, UK

Introduction

Genetically modified mice and (to a lesser degree) rats are frequently used as models for human cardiac disease. Since the genomes of both mouse and humans have now been fully analyzed, major research programs are currently underway worldwide to investigate systematically the function of specific genes by overexpression, deletion or mutation of these genes and their products in mice (e.g. [1] for review). These recent advances in gene manipulation have lead to a new era of cardiovascular research, and new animal models of cardiovascular disease are appearing at a rapid rate [2–4]. The phenotypic effects introduced by these transgenic models range from the absence of any overt abnormalities to severe anatomical, functional, or metabolic malformations during development causing premature death *in utero* or soon after birth [5].

Some phenotypes are only manifested under chronic myocardial stress conditions. Thus, dedicated surgical techniques, such as transverse aortic constriction (TAC) or ligation of the left coronary artery (LAD) have been developed in rodents in order to model cardiac disease conditions that resemble those found in patients with heart disease. Specifically, Aortic constriction in rodents causes pressure overload in the heart resulting in progressive hypertrophy of the left ventricle as a compensatory mechanism, eventually leading to heart failure [6,7]. Ligation of the LAD causes acute myocardial infarction resulting in ventricular dilatation, depression of cardiac function, and remodeling of the non-infarcted residual myocardium, finally leading to an increased mortality due to chronic heart failure (e.g. [8] for review).

The development of methods to examine the physiological effects of gene alteration in mice, i.e. techniques for cardiovascular phenotype characterization, or the consequences of surgical myocardial damage, have not kept up with the speed at which these animal models are being generated. In fact, a better understanding of gene function will only come from more sophisticated phenotype characterisation, and a lack of adequate murine phenotyping tools is now a major limitation: The electrocardiogram (ECG) only provides limited information. Haemodynamic measurements using microtip catheters, while highly informative, are invasive, technically demanding and in mice with a total blood volume of 1–2 ml the slightest surgical blood loss leads to haemodynamic instability. Echocardiography, whether 1D (M-mode) or 2D, is frequently used to characterize hearts of mice and rats, because it is an affordable and relatively fast technique, but it relies on geometric assumptions for volume calculation, has a low reproducibility and only yields a limited number of parameters. *Ex vivo* examinations such as histological sectioning are time consuming and do not provide any insights into cardiac function or the metabolism of the heart.

Magnetic resonance imaging (MRI) and spectroscopy (MRS) are non-invasive techniques that use intrinsic contrast mechanisms and are capable of obtaining true 3D information on the heart and the vascular system. In humans, cardiovascular magnetic resonance (CMR) techniques have been developed towards a “One-Stop-Shop”, where information on cardiac anatomy, function, perfusion, viability, metabolism, and the vasculature may be obtained in a single examination. We have postulated that a similar approach is feasible in experimental cardiovascular research, and that MRI and MRS are ideal methods to investigate comprehensively the normal and diseased cardiovascular system in mice and rats.

However, the precise characterization of the rodent heart by MR methods is technically extremely challenging. The mouse heart is approximately only 1/2000th the size of the human heart, and beats about 10 times faster. Thus, spatial and temporal requirements are demanding, and MRI/MRS methods have to maximize speed and spatial resolution in order to allow for a successful investigation of the cardiovascular system. In this chapter, we will describe how to assess global and regional function of the rodent heart, and how information about cardiac metabolism and the vasculature can be obtained. However, we will first explain the methodological requirements for the application of cardiovascular MRI and spectroscopy in mice and rats.

Methods and Requirements

The length of a cardiac cycle (RR-interval) is typically 100–150 ms in mice (for heart rates between 400–600 beats per minute (bpm) – compared to $\approx$1 s in humans at $\approx$60 bpm), and is 133–200 ms in rats (for heart rates between 300 and 450 bpm). The diastolic phase, i.e. the

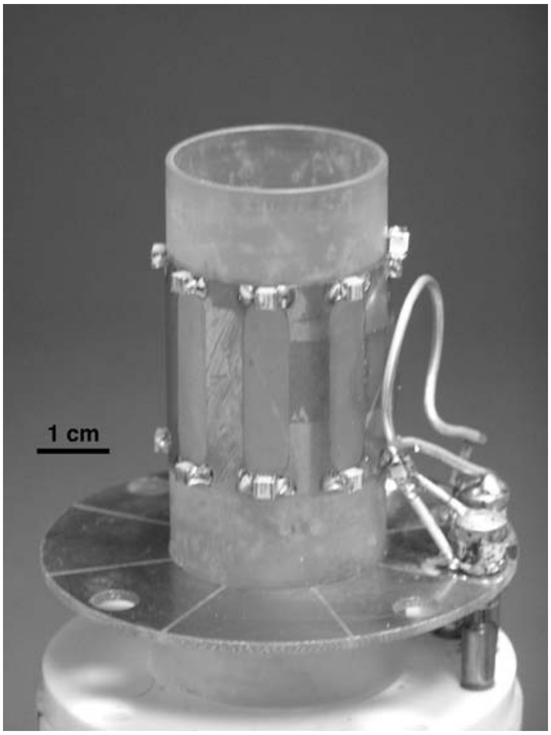

Fig. 1. Volume RF-coil for CMR in mice at 11.7 T. The characteristic leg structure has given this RF-coil the name "birdcage coil". The high-pass birdcage coil as shown in this figure has an inner diameter of 28 mm and is used for mice with a body weight of 17–25 g. It consists of eight legs that are orientated in parallel to the B_0-field with 16 capacitors distributed symmetrically between the legs in the two end rings. (See also Plate 69 on page XLVII in the Color Plate Section.)

part of the cardiac cycle with minimal cardiac motion, is about 30–40 ms long. Therefore, any MR method has to utilize short echo times (T_E) and repetition times (T_R). Furthermore, the left ventricular wall in healthy mice has a thickness of about 1 mm, and the ventricular volumes range between a few microliters (in end-systole) up to 100 μl (in end-diastole). Therefore, strong (>500 mT/m), fast switching (100–200 μs) gradient systems are necessary to apply high-speed sequences at high spatial resolution. However, such gradient switching can cause heating, and so an efficient cooling system is required to prevent temperature changes being transferred to the animal, which would result in altered cardiac function.

Today's clinical MR scanners commonly have static magnetic field (B_0) strengths of 1.5–3 T, whereas animal systems range between 4.7 and 17.6 T. The signal-to-noise ratio (SNR) of an MR experiment improves with increasing B_0. Ultra-high-field magnets are important for cardiac experiments in rodents as the gain in SNR allows for achieving the necessary spatial and temporal resolution (the SNR decreases with increasing resolution). Additionally, dedicated radio-frequency (RF) coils that are optimized in geometry and loading for a particular animal size, are required to obtain maximal SNR. Volume coils (i.e. birdcage coils [9]) are commonly used for mice as they provide an excellent homogeneity of the RF-field. They can also be applied in "quadrature mode", resulting in an additional increase in SNR of a factor up to $\sqrt{2}$ [10]. A picture of a birdcage coil used for cardiac MR in mice at 11.7 T is shown in Figure 1. In rats, a combination of body coil for transmit and surface-coil for receive are typically used [11,12]. A similar configuration would provide more efficient mouse imaging, but the implementation is very difficult owing to the small size.

Next to hardware and MR methods, careful consideration must be given to maintaining stable animal physiology throughout an experiment. Dedicated animal cradles, optimized in diameter and length, are required. An example illustrating such a set-up is shown in Figure 2. They typically comprise a nose cone for delivery of anaesthetic gases, a scavenging line for anaesthetic gas recovery, a temperature control system—consisting of a heating blanket and a thermocouple—for maintaining a constant body temperature, and ECG and respiratory motion sensing capabilities for physiological gating. RF filters may be useful to eliminate contamination of the MR signal by external RF noise pick-up. Additional lines are required if the animals are to be ventilated artificially, and if drugs or MR contrast agents need to be administered. The animals have to be secured within the cradle using surgical tape. Special care should be taken not to distort or compress their abdominal or chest regions.

The heart rate of the animal is influenced by the body temperature and by the depth of anaesthesia. A core body temperature of 37 °C has to be maintained by supporting the temperature regulation of the animal in order to ensure physiologically normal conditions. This can be achieved using special blankets that are heated by warm air or water (air has the advantage over water that it is MR invisible and it does not interfere with the RF-coil). Furthermore, the lowest possible anaesthetic level should be applied in order to minimize depression of cardiac function by anaesthesia [13]. To achieve this, anaesthetic gases are commonly used for cardiac studies as the dose can be easily titrated for the individual animal whilst in the magnet. In particular, Isoflurane causes the least cardiac depression and represents the anesthetic of choice for this purpose [14]. Due to suppression of the eye-closure reflex during anesthesia, ointment must be applied to the eyes in order to keep them moist.

The recording of the ECG and the respiratory signal is not only necessary to monitor the animal inside the magnet (where visual assessment is not possible), but also to minimize the influence of cardiac and respiratory motion on the MR experiment. It is well recognized that motion artifacts

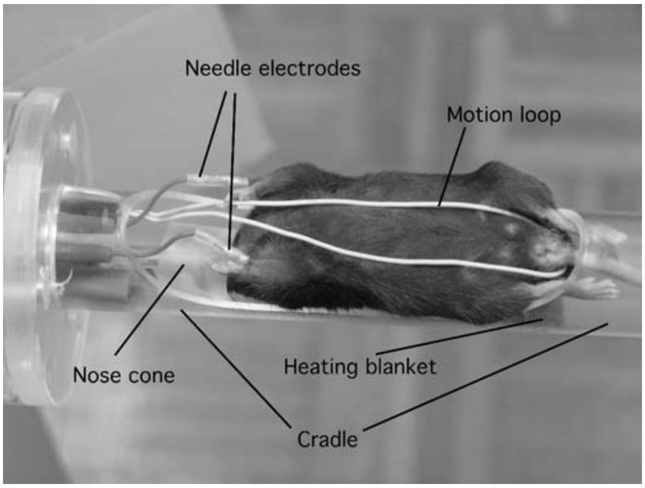

Fig. 2. Illustration of a set-up used for CMR in rodents. The shown set-up consists of the animal cradle, which is equipped with a nose cone, needle electrodes for deriving the ECG and a conductor loop for detecting respiratory motion. The animals are placed onto a heating blanket to maintain a constant body temperature of 37 °C throughout the MR experiment. (See also Plate 70 on page XLVII in the Color Plate Section.)

become more pronounced with increasing magnetic field strength [15]. Figure 3 illustrates this influence on cardiac MR imaging in mice at 11.7 T. The data shown in this figure were acquired under various gating strategies.

Front-paw-mounted needle electrodes, inserted subcutaneously into the front limbs of the animal, or surface electrodes are used to derive the ECG. A good coupling between the electrodes and the animal is crucial to obtain

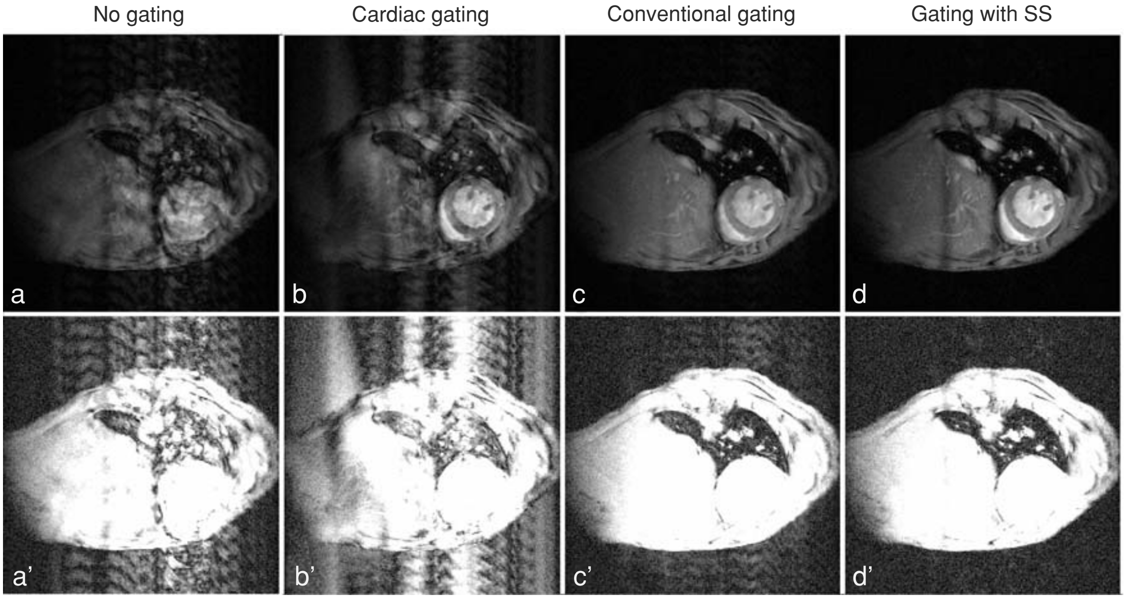

Fig. 3. Motional influence on cardiac imaging in mice at ultra-high magnetic fields. Transverse gradient echo images through the heart of a normal mouse acquired at 11.7 T. Both rows are identical with the image intensity in the bottom row (a′–d′) increased to a maximum level in order to reveal low-level artifacts. Each column corresponds to a different gating strategy (from left to right): (a, a′) No gating, (b, b′) cardiac gating, (c, c′) respiratory gating without and (d, d′) with steady-state maintenance (SS) during respiration [16]. Each row is scaled to the same range of image intensity. The vertical signal voids present in the images are due to saturation effects from adjacent oblique slices that were acquired in the same experiment. Note the low-level artifacts visible in panel c′. They are caused by interrupting the steady state during respiration and their strength depends on the MR sequence and parameters used in an experiment. Scale bars: 2 mm.

robust ECG-traces that can be triggered from. Respiration can be monitored using pressure pads or conductor loops mounted on top of the chest and the abdomen of the animal as shown in Figure 2. Adequate measures have to be provided to suppress any interference due to gradient switching with the ECG and respiratory signals. An electronic gating device serves as an interface between the animal, the user and the MR-system and allows for synchronizing the experiments to the cardiac cycle and for interrupting the data acquisition during respiration (i.e. respiratory gating). This device is offered by various manufactures or can be home built. Care has to be taken when disrupting the steady state of the spin system during respiration, because this can be the source of another—non-motion related—image artifact (see Figure 3 c′). Cassidy *et al.* demonstrated a simple way of maintaining steady state of the spin system during respiration: the MR sequence was continued throughout respiration with the same timing as determined by the heart beat but without acquiring data. The decision to acquire data or to maintain steady state is made during run-time without any additional user-input being required [16].

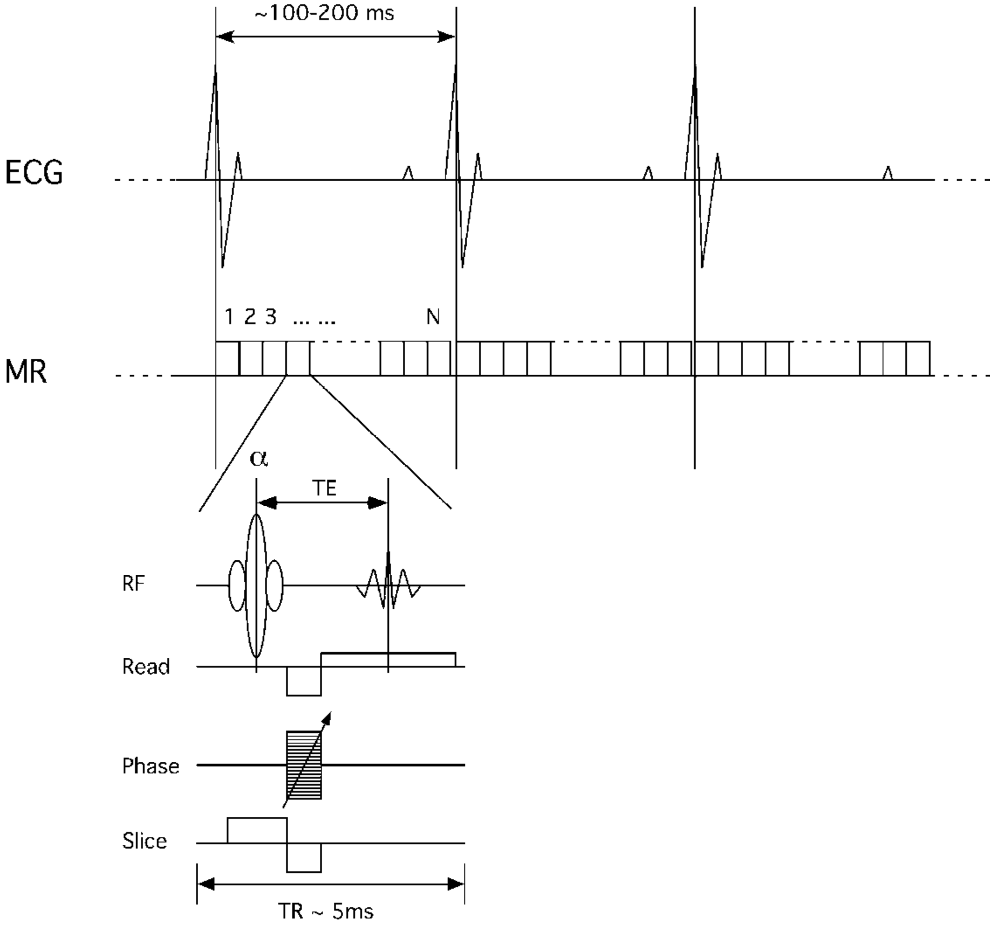

Fig. 4. Diagram of an MRI cine sequence used in rodents. Fast, spoiled gradient echo sequences are typically used for cardiac imaging in rodents. After the detection of the R-wave in the ECG, the same *k*-space line is acquired repeatedly with a constant value for the phase encoding gradient. The number of frames N per cardiac cycle depends on the sequence timing and the heart rate of the animal and ranges between 15–30 frames. The illustrated scheme is repeated in the next cardiac cycle with a different value for the phase encoding gradient. Thus, the product of number of phase encoding steps times number of averages cardiac cycles are required in total to obtain a full cine data set for one slice. If respiratory gating is employed, the scheme is interrupted during respiration and the imaging time is prolonged.

Global Cardiac Function

The application of high-resolution MRI in multiframe mode (cine imaging, cine-MRI) allows for non-invasive quantification of left-ventricular mass and volumes in mice and rats. Fast, 2D spoiled gradient echo type sequences are commonly applied continuously throughout the cardiac cycle and provide high contrast between blood and myocardium. Refocused steady-state free-precession sequences, as frequently used for cardiac MRI on human scanners, are more difficult to employ at ultra-high magnetic fields due to their sensitivity to susceptibility differences. Figure 4 shows a schematic depiction of a cine experiment in rodents. Repetition times of less than 5 ms per frame freeze cardiac motion and result in 15–30 frames per RR interval (depending on the heart rate). The echo times are B_0-field dependent and chosen such that lipid- and water-protons have an opposite phase to enhance the contrast between different tissue types [17]. The values range between 1 and 2 ms. The flip-angle of the sequence needs to be adjusted according to the chosen repetition time and respective relaxation times in order to maximize the contrast between blood and myocardium. The in-plane image resolution (before image interpolation) in mice is typically around 100–200 µm at a slice thickness of 1 mm, and in rats about 200–300 µm at a slice thickness of 1–1.5 mm. Seven to ten slices are required to cover the entire mouse heart from base to apex. Accordingly, 10–20 slices are needed to image the entire rat heart. Studies at magnetic field strengths up to 7 T commonly use cardiac gating only, whereas additional respiratory gating is essential at higher magnetic field strengths to obtain virtually artifact-free, high-quality images, as we have demonstrated quantitatively [18]. A cine study of the entire mouse heart can currently be accomplished in well under one hour, and in rats within approximately 90 mins—depending on the required spatial resolution, and whether or not respiratory gating has to be applied or not.

Figure 5 shows examples of end-diastolic and end-systolic frames in short-axis and long-axis orientations of a normal mouse heart, acquired at 11.7 T. The end-diastolic frame is characterized as the one with maximal left-ventricular volume, and the end-systolic frame the one with minimal left ventricular volume, respectively. The mainly stationary tissue (relative to the imaging slice), such as cardiac or skeletal muscle, is saturated by the repeatedly applied RF-pulses and subsequently appears dark. The blood provides high signal in these images due to the inflow effect of blood into the imaging slice (bright-blood images). It has to be noted that the contrast can be inverted if the imaging sequence is combined with dedicated black-blood techniques [19,20]. However, this approach usually provides a reduced temporal resolution throughout the cardiac cycle and requires longer acquisition times to gain sufficient signal-to-noise. The left ventricle has a characteristic doughnut shape in the short-axis view (Figure 5a, a′), which is orientated orthogonally to both long-axis views: the four-chamber view (Figure 5b, b′) and the two-chamber view (Figure 5c, c′). The papillary muscles do not appear as connected to the ventricular muscle in this end-diastolic frame (Figure 5a) and are seen as dark spots inside the bright ventricular cavity.

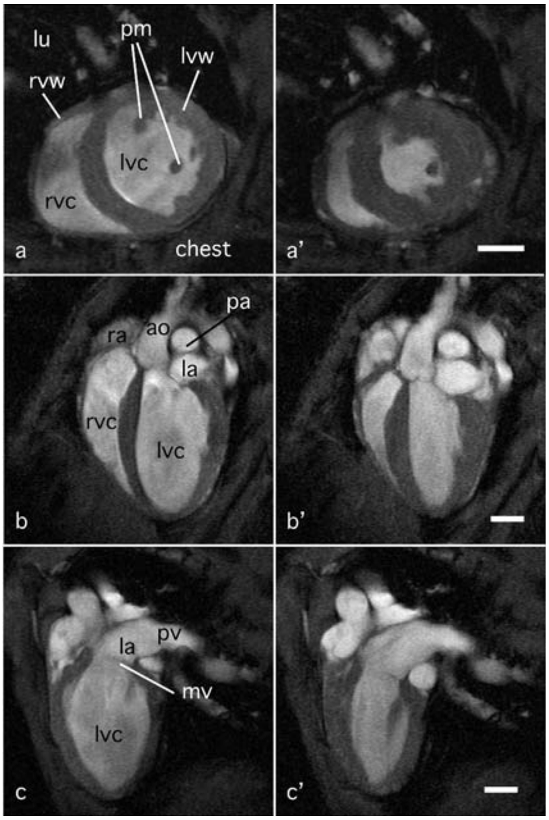

Fig. 5. Cine-images of normal mouse heart. Mid-ventricular end-diastolic images through a normal mouse heart in the (a) short-axis orientation, (b) the four-chamber and (c) the two-chamber long-axis orientation; both long-axis views are orthogonal to the short-axis orientation. The primed panels correspond to the respective end-systolic frames. Abbreviations: lvc, rvc—left/right ventricular cavity; lvw, rvw—left/right ventricular wall; pm—papillary muscle; lu—lungs; la, ra—left/right atrium; ao—aorta; pa, pv—pulmonary artery/vein; mv—mitral valve. Scale bars: 2 mm.

Manual or semi-automatic segmentation of both the end-diastolic and the end-systolic short-axis frame for every slice allows for a quantitative analysis of left ventricular mass and function in rodents. Figure 6 shows the

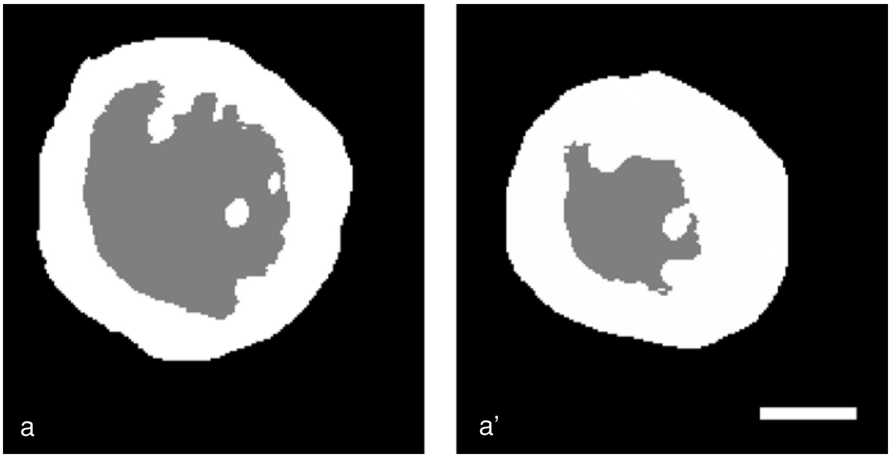

Fig. 6. Quantitative image analysis. Segmentation of end-diastolic and end-systolic frames shown in Figure 5a, a′ allows for quantitative measurement of left ventricular mass (white area) and volume (grey area) and subsequently calculating cardiac functional parameters. Note that the papillary muscles are counted towards the ventricular mass and *not* to the cavity volume. Scale bar: 2 mm.

result of the image segmentation process: the white compartment corresponds to myocardial volume and the grey compartment to the ventricular cavity volume. Ventricular mass is obtained by multiplying the myocardial volume with the density of myocardial tissue (1.05 g/cm^3 [21]). Table 1 lists all relevant parameters that can be derived from a cine experiment. The quantitative analysis of the cine images is highly reproducible with low inter- and intra-observer variability that improves with increasing field strength [18].

This technique has been applied in several studies to investigate cardiac function of normal mice [22–25] and rats [11, 26]. It has also been used to study developmental changes in cardiac function and mass from neonatal to adult mice [27].

Table 1: Relevant cardiac functional parameters

Acronym	Description	Definition	Unit	Normal Mouse Heart*
HR	Heart rate	Beats per minute	bpm	429 ± 24
ESV	End-systolic volume		µl	15.7 ± 1.2
EDV	End-diastolic volume		µl	43.0 ± 3.9
EDM	End-diastolic mass		mg	57.1 ± 4.2
SV	Stroke volume	EDV-ESV	µl	27.4 ± 3.4
EF	Ejection fraction	100% · SV/EDV	%	63.5 ± 2.9
CO	Cardiac output	SV · HR	ml/min	11.4 ± 1.2

* Taken from [18].

Applications in transgenic mice have, for example, been shown in a model of cardiac hypertrophy [28], mice with myocardial overexpression of tumor necrosis factor-α [29,30], and adult cardiomyocyte-specific VEGF knockout mice [31].

We have used this technique to investigate the effect of orthostasis in mice and rats. Experimental ultra-high-field MR systems are commonly equipped with a vertical bore magnet for engineering reasons. Although from a physiological point of view this is the preferred design for experiments in isolated perfused organs and on aqueous solutions, animals have to be positioned in an upright position for *in vivo* studies on such MR systems. It is well recognized that it is impractical to investigate larger mammals and humans in the vertical position, as the effect of orthostasis reduces venous return, LV volumes and cardiac output [32]. We demonstrated that MR systems with a vertical bore can generally be used to measure cardiac function in both, mice and rats, within approximately 1–1.5 h [18,26]. However, longer experiments may best be done in horizontal position due to detectable changes in volumes, ejection fraction and cardiac output occurring over prolonged experimental periods [33].

Cine imaging can also be used to characterize surgical animal models of human cardiac disease non-invasively. In chronically failing hearts of rodents [34–37], the degree of failure (as indicated by the ejection fraction; hearts with an EF <45% may be defined as failing) can be assessed with cine-MRI. Furthermore, in the chronic myocardial infarct (MI) model, hearts can also be stratified according

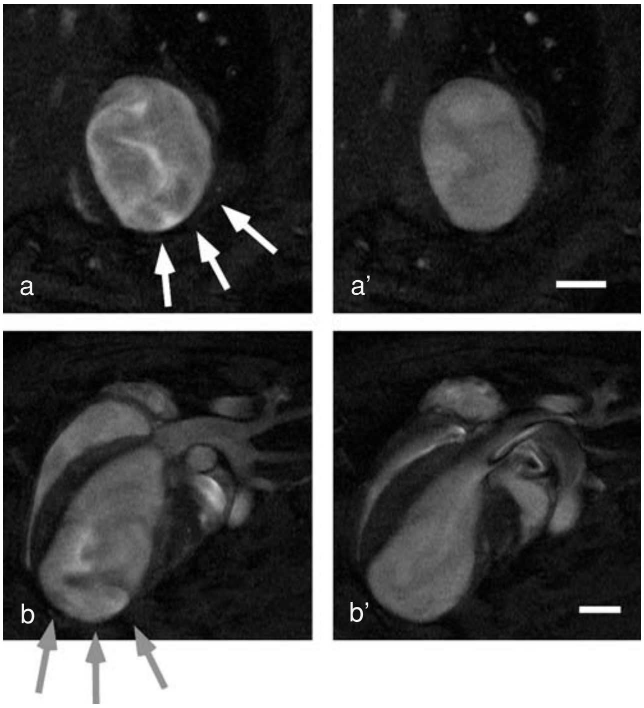

Fig. 7. Cine-images of failing mouse heart. Mid-ventricular end-diastolic images through a failing mouse heart in the (a) short-axis orientation and (b) the four-chamber long-axis orientation. The primed panels correspond to the respective end-systolic frames. The arrows indicate the infarcted area, which is characterized by akinesis and wall thinning. Scale bars: 2 mm.

to their infarct size, which can be calculated according to:

$$\text{Infarct size} = \frac{1}{\text{NSLICES}} \sum_{i=1}^{\text{NSLICES}} \frac{1}{2}\left(\frac{I^i_{\text{epi}}}{T^i_{\text{epi}}} + \frac{I^i_{\text{endo}}}{T^i_{\text{endo}}}\right) \times 100\% \quad (1)$$

(With T_{Epi}, T_{Endo}—total endo- and epi-cardial circumference of left ventricle; I_{Epi}, I_{Endo}—endo- and epi-cardial length of infarcted tissue, respectively). The infarct is characterized as the area of akinesis. The multiframe capability is crucial for these measurements in order to distinguish between normal and infarcted tissue. While “hibernating” tissue, i.e. viable tissue that does not actively contract, cannot be identified from these cine-images, this does not constitute a problem in the chronic coronary ligation model in mice or rats, where long-term hibernation does not occur. A slice across a failing murine heart (infarct size: 40%) in short-axis orientation is shown in Figure 7. The arrows indicate the wall thinning in the infarcted area. Only small changes in ventricular volumes can be detected between both frames (total ventricular volumes—EDV: 153 µl, ESV: 117 µl) yielding a substantially reduced EF of 24%.

In animals with constriction of the transverse aorta (TAC), the degree of hypertrophy and failure can be measured quantitatively by cine-MRI. Figure 8 shows the end-diastolic frame of mice (a) without and (b) with TAC. The left ventricular wall in (a) is clearly hypertrophied compared to the control animal. Quantitative analysis yielded a ~275% increase in left-ventricular mass in this case at a deteriorated cardiac performance (EF = 35% vs. 64% for the healthy mouse heart). However, considerable variation in the hypertrophic response and in the time to heart failure has been observed in this model, even when same sex and inbred littermates are used. Our recent work has shown that variations in the minimal cross-sectional area of the aorta—as measured by MRI—are one factor responsible for the variability of this model [38]. This would not be possible using echocardiography, as there is no available acoustic window for imaging the aortic arch. Therefore, MRI provides a unique opportunity to stratify animals with TAC according to their minimal cross-sectional aortic area.

In summary, MRI can be applied repeatedly to measure growth curves of the heart or to follow-up after procedures, as demonstrated in this section. The high-resolution and non-invasive nature of this technique are important advantages. They enable a reduction in the number of animals required for each study, which is a major principle of good animal welfare practice. In addition, each animal can also serve as its own control, providing a more powerful statistical analysis in an inhomogeneous population.

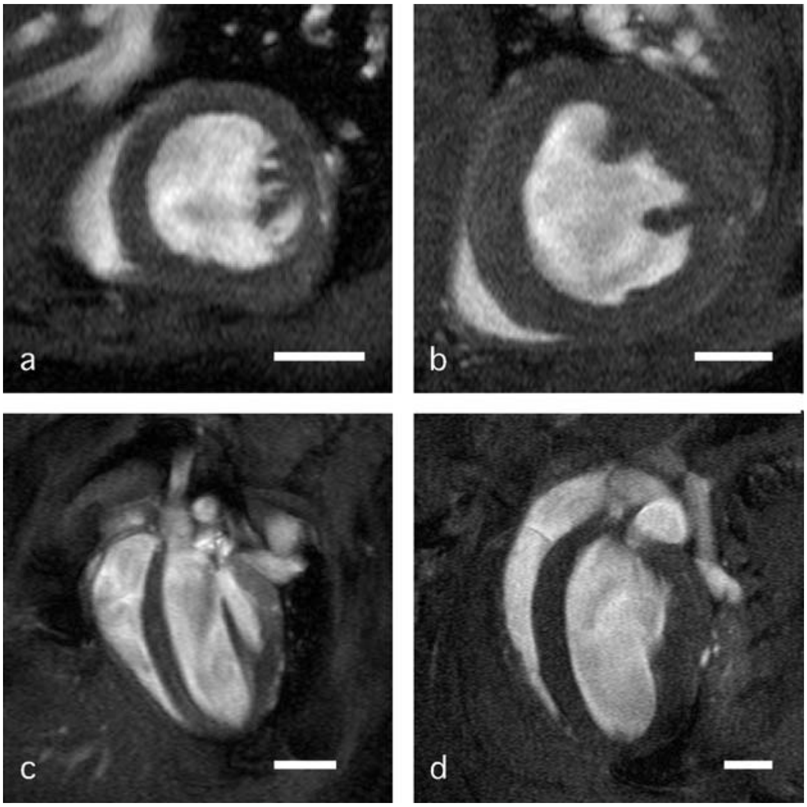

Fig. 8. Cine-images of mouse with TAC. Mid-ventricular end-diastolic images across a normal mouse heart in (a) short-axis and (c) long-axis orientation. (b, d) Corresponding views of a mouse with TAC illustrating the increase in myocardial mass (hypertrophy). Scale bars: 2 mm.

Myocardial Tissue Contractility

Conventional cine imaging, as described in the previous section, allows for assessment of global cardiac function as well as bulk motion of the myocardium. However, analysis of transmural wall motion becomes necessary in models where regional variations of contractile function occur, such as the chronic MI model. Two basic approaches have been used to visualize and measure wall motion regionally: In myocardial tagging, a grid of signal voids is generated either by selective saturation [39] or by a modulation of the magnetization by gradient fields (termed SPAMM: SPAtial Modulation of Magnetization) [40]. The tags are then tracked throughout the cardiac cycle by a multi-phase sequence similar to the one shown in Figure 4. A quantitative analysis of the tag-movement ("strain analysis") allows for calculating the minimum and maximum principal stretches, their orientation and the minimum and maximum principal strains [41,42].

Myocardial tagging has been applied to rodents in order to investigate left ventricular torsion in mice [43]. Zhou *et al.* used SPAMM to characterize normal mouse heart function [24]. Furthermore, Epstein *et al.* demonstrated significant contractile dysfunction in murine hearts one day after infarction in the infarcted, the adjacent, and the remote zone [44]. Although this method allows for an easy visualization of cardiac motion, its major limitation is the inherent low spatial resolution, because a clear distinction between the tags in the image is required. The tag spacing in the murine studies ranged between 0.7 mm [24,44] and 1.2 mm [43], which is in the order of the normal myocardial wall thickness in a mid-ventricular short-axis slice across a mouse heart. An example of myocardial tagging in the mouse is shown in Figure 9.

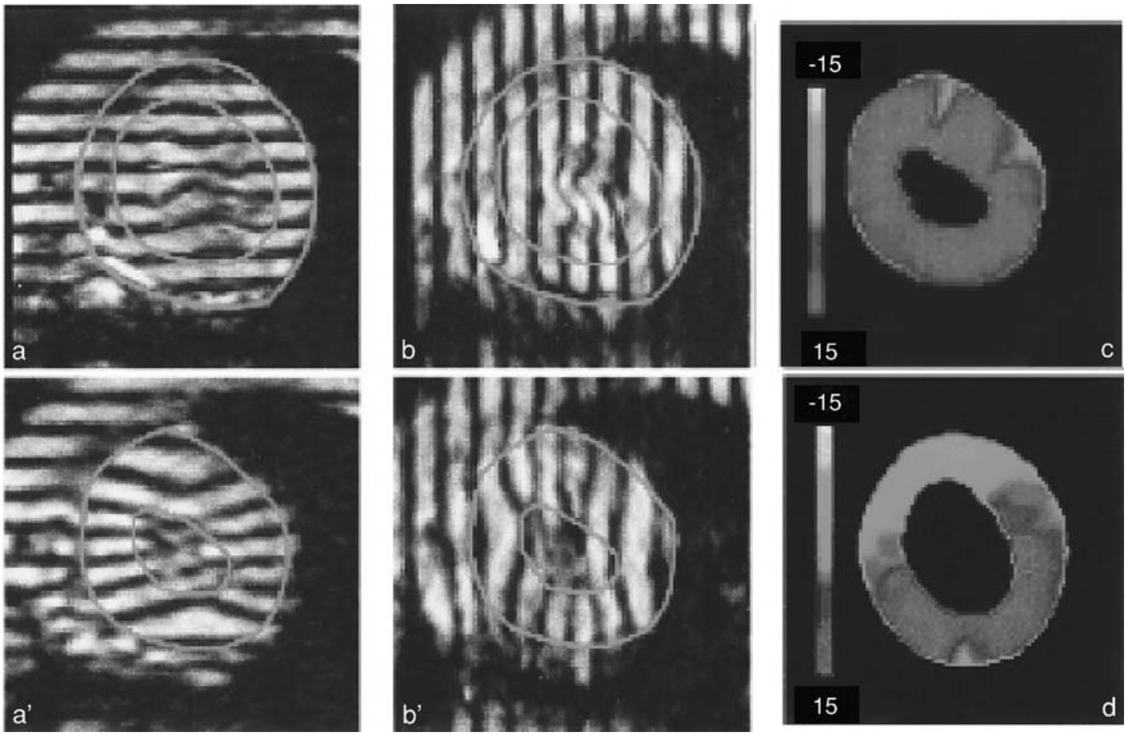

Fig. 9. Myocardial tagging in the mouse heart. Normal mouse heart in end-diastolic phase with (a) horizontal and (b) vertical tags. The primed panels correspond to the respective end-systolic frames. The map in panel c shows the percentage of circumferential shortening (% CS) for this mouse obtained from a quantitative analysis of the tag movements. The homogeneous pattern is distorted in a mouse with myocardial infarction (panel d). (Taken from [44].) (See also Plate 71 on page XLVII in the Color Plate Section.)

A second approach involves encoding of cardiac motion by the phase of the MR-signal (phase contrast (PC) MRI, [45–49]). In principle, a similar sequence as shown in Figure 4 can be used, but with additional bipolar gradient pulses fitted between the RF-pulse and the data acquisition. The zero-order gradient moment M_0[1] generated by the bipolar gradients is zero with a non-vanishing first-order gradient moment M_1. The additional phase accumulation Φ' is then given by:

$$\Phi' = \gamma M_1 v, \qquad (2)$$

where γ is the gyromagnetic ratio for protons given by $\gamma = 42.58$ MHz/T and v the mean velocity over the encoding interval. Thus, stationary spins remain unaffected by the bipolar gradients whereas moving spins accumulate a phase that is proportional to their velocity. At least two scans are acquired in each direction with different first-order gradient moments. The phase images are subsequently subtracted to minimize phase accumulation caused by B_0 inhomogeneities and RF penetration effects [50,51]. Alternatively, one scan with $M_1 = 0$ (i.e. bipolar gradients turned off) is acquired to obtain a phase reference.

Streif *et al.* investigated normal and infarcted mice—one week post-ligation of the LAD—at 7 T using PC-MRI [52]. They applied a maximum first-order moment of $M_1 = 93$ μTs^2/mm during an echo-time of 3 ms. In Figure 10, velocity maps obtained at mid-systole are shown for a normal and an infarcted mouse (anterior wall infarct), with a spatial resolution of 234 μm in plane and a slice thickness of 1mm.

Applying this method in multiphase mode allows for a temporally resolved, quantitative mapping of the cardiac motion throughout the entire heart cycle. Furthermore,

---

[1] The nth order gradient moment is given by: $M_n = \int_{t_0}^{t_1} G(t) \cdot t^n dt$, with t the time and $G(t)$ the gradient, that has been switched between t_0 and t_1.

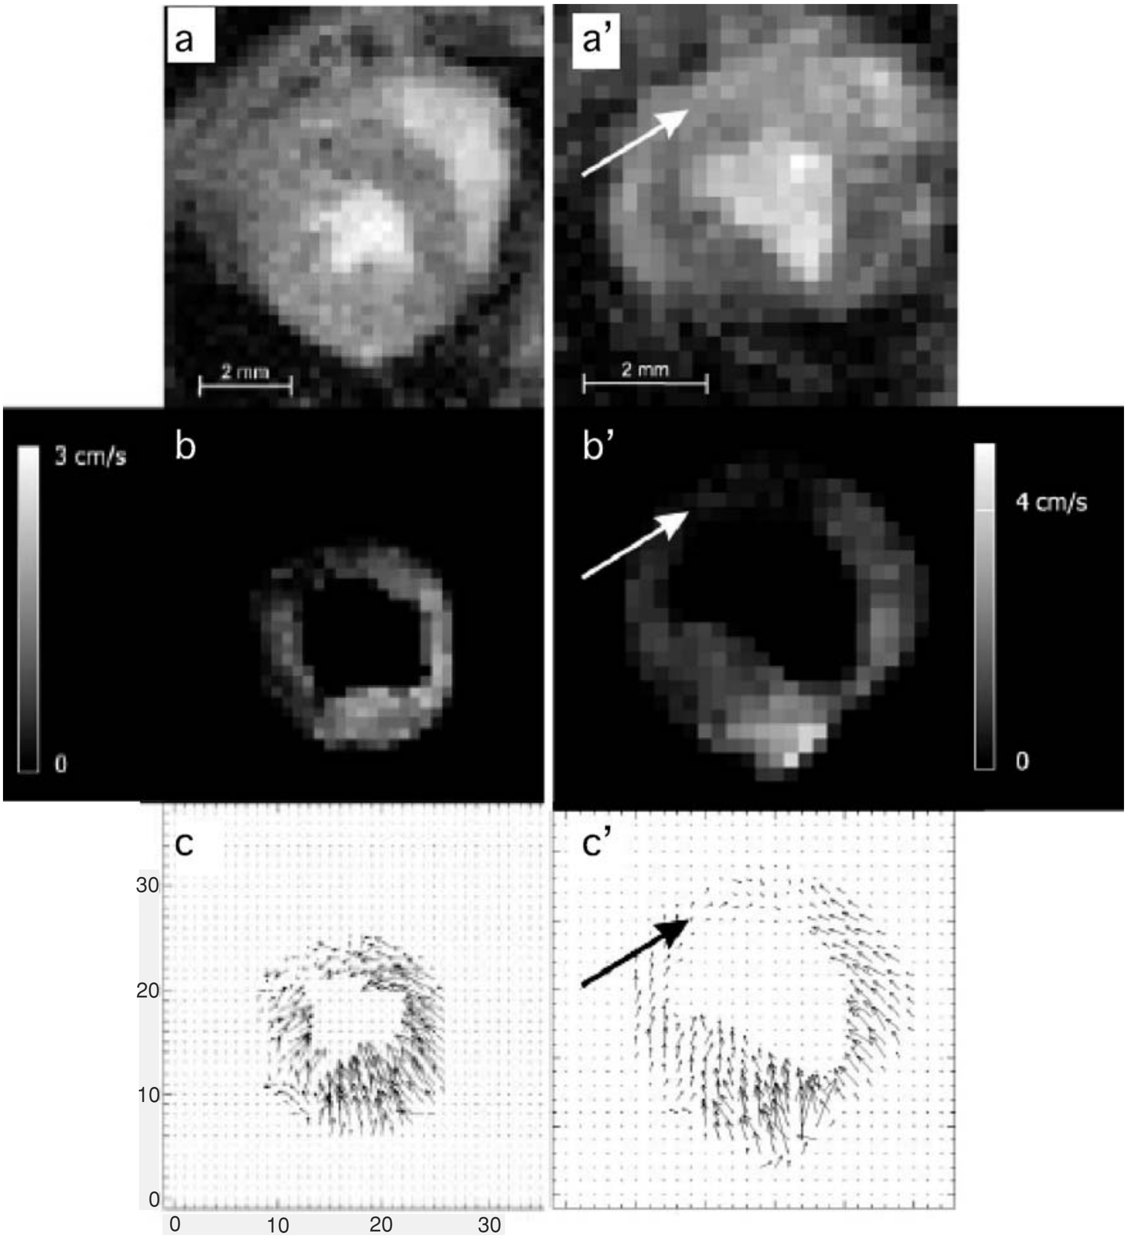

Fig. 10. Phase-contrast imaging in the mouse heart. Left column: (a) Mid-ventricular end-systolic cine image across a normal mouse heart. (b) Velocity map obtained from the vector diagram in (c). Right column: Corresponding images for a mouse heart with a myocardial infarct in the anterior wall as indicated by the arrows. This area shows substantially decreased contraction. (Taken from [52]).

global functional data are obtained in the same experiment. However, this method encodes only short periods of motions and large first-order gradient moments are required to encode low velocities. Furthermore, PC-MRI is sensitive to phase distortions caused by imperfect gradient performance or uncompensated motion such as blood flow, cardiac and respiratory motion. In particular, longer echo times may be required to generate sufficiently strong first-order gradient moments, which could become more critical with increasing magnetic field strengths.

An alternative approach proposed by Aletras *et al.* is called Displacement ENcoding with Stimulated Echoes (DENSE) and combines the advantages of both methods described above [53–55]. DENSE is in principle based on a stimulated echo sequence in which a phase distortion is generated by a gradient pulse G_1, applied for a time t_1 after an initial RF-excitation. A second RF-pulse stores the magnetization along z-direction and is followed by a mixing period TM (to assess systolic displacement, this time is typically the time between the begin and the end of systole) in which the displacement is encoded. A third RF-pulse brings the magnetization back into the transverse plane and the phase distortion is rewound by repeating the same gradient pulse G_1. Both gradient pulses are perfectly balanced for stationary spins, which therefore acquire no net phase. However, spins that have moved during TM by a distance Δx, acquire an additional phase of:

$$\Phi_1 = \gamma G_1 t_1 \Delta x, \tag{3}$$

The sequence is repeated with different values for G_1 in the same spatial direction with the displacement Δx being obtained from the phase difference between these images, and also in different directions. Similar to tagging, the 2D displacement data are then used to calculate the strain tensor, which allows for calculation of the circumferential shortening and the radial thickening of the hearts.

Recently, Gilson *et al.* used this technique to demonstrate systolic dysfunction in mice one day post-infarction [56]. They reported a close agreement of strain values obtained from DENSE with those measured by conventional tagging. Importantly, the spatial resolution in the DENSE study was nearly one order of magnitude higher compared to the tagging study [44,57]. This method has been developed further and extended to a multislice [58] and a 3D [56] method with displacement encoding in three dimensions. This enabled assessment of myocardial strain in both, short- and long-axis directions of the heart. Experimental times varied between 50 min for multislice [58] and 2.5 h for 3D methods [56].

In contrast to PC-MRI, the phase in each pixel is used here to measure displacements rather than velocities. Although this simplifies the calculation of the strain maps [59], the displacement is equivalent to the mean velocity during the encoding time. One major limitation of DENSE is the reduced SNR, which so far allowed only single-phase imaging in mice [57]. However, DENSE-MRI in cine mode has recently been reported in humans [60]. A main difference to PC-MRI is the time over which any motion is encoded. Specifically, an average displacement that takes place during a period within the cardiac cycle is measured by DENSE without any information of global cardiac function. PC-MRI, however, provides a dynamic picture of motion throughout the entire cardiac cycle and inherently includes the capability to measure cardiac function globally.

It is anticipated that these methods for measurement of myocardial tissue function will be of widespread use in rodent models of altered regional contractility.

Multinuclear MR Spectroscopy

For MRI, the signals of water and fat protons are interrogated. The tissue water concentration in the heart muscle is about 100 M. MRS, however, interrogates the signals of metabolites, which are present in many orders of magnitude lower concentration (around 5–20 mM). Furthermore, MRS using nuclei other than protons, such as ^{13}C or ^{31}P, is additionally hampered by a lower MR sensitivity. Taking the natural abundance into account, the MR sensitivity is a factor of 1.8×10^{-4} for ^{13}C and of 6.6×10^{-2} for ^{31}P lower compared to protons. Therefore, low metabolite concentrations in the presence of cardiac and respiratory motion, and the small size of the heart pose major challenges for implementing MRS methods in rodent hearts *in vivo*. ^1H-MRS is additionally hampered by the presence of a dominating water signal, which needs to be suppressed sufficiently in order to detect the weak metabolite signals. Thus, the signals we can detect with MRS are fundamentally much weaker than those of MRI, making it a relatively low-resolution technique.

An increasing static magnetic field strength is particularly beneficial for MRS, because it not only improves the signal-to-noise, but also the spectral resolution. This can facilitate the suppression of the dominant water signal in ^1H-MRS, the separation and identification of neighboring resonances and, therefore, potentially improve the accuracy of quantitative analysis of the spectra.

So far, multinuclear MRS has mainly been applied to the model of Langendorff-perfused mouse and rat heart [61–64], as well as in dogs [65] and humans [66–72] *in vivo*. The application of this technique to rodent hearts *in vivo* would enable the investigation of cardiac metabolism under physiological and pathophysiological conditions. Importantly, the physiological relevance of the isolated, perfused mouse heart model is limited because

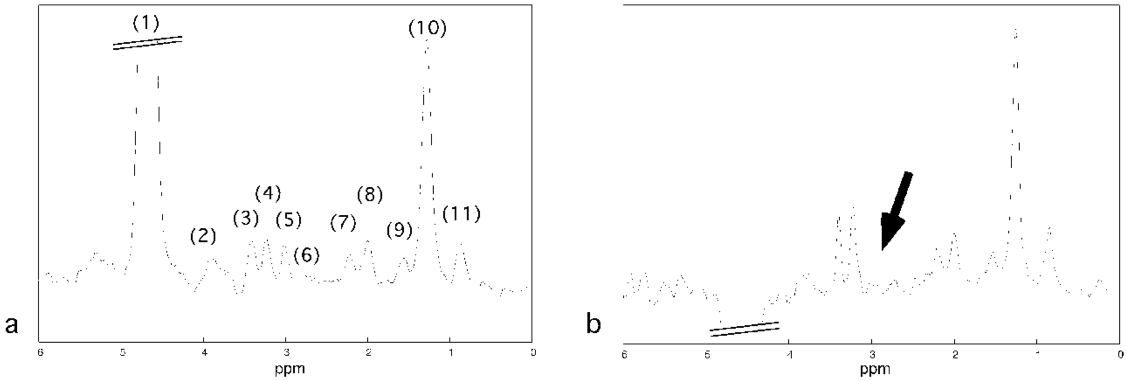

Fig. 11. Cardiac ^{1}H single voxel MRS in mice *in vivo*. (a) ^{1}H-spectrum from a 2 μl voxel positioned in the interventricular septum of a wild type mouse *in vivo*. The resonances were assigned according to ref. [61] and referenced relative to the residual water signal (peak (1)), which was set to 4.7 ppm. (2) (P)Cr – CH_2, 3.88 ppm; (3) taurine, 3.38 ppm; (4) carnitine, 3.21 ppm; (5) (P)Cr – CH_3, 2.99 ppm; (6) unassigned, 2.72 ppm; (7) glycerides ($C_{\alpha}H$), 2.20 ppm; (8) unassigned, 2.0 ppm; (9) glycerides ($C_{\beta}H$), 1.55 ppm; (10) glycerides ($(–CH_2)_n$), 1.26 ppm; (11) glycerides terminal methyl, 0.85 ppm. (b) Spectrum from a guanidinoacetate *N*-methyltransferase deficient mouse (GAMT$^{-/-}$), where no creatine was detectable (black arrow). Both spectra consisted of 512 averages and were scaled equally.

in vivo workload levels cannot be achieved [73]. Due to its non-invasiveness, these studies may also be repeated throughout the life span of an animal, before and after an intervention, or during progression of disease.

In some circumstances, a qualitative or semi-quantitative analysis of the MRS data is sufficient. This involves either the presence or absence of a particular resonance in the MR spectrum (for example, the detection of lactate as a marker for anaerobic metabolism), or the calculation of metabolite ratios (i.e. PCr/ATP in ^{31}P-MRS). In general, however, an absolute-quantitative approach is desirable. This requires the use of a concentration standard (internal or external), a quantitative analysis (i.e. fitting) of the MR data and the knowledge of several parameters intervening into absolute quantification, such as MR relaxation parameters, RF-coil sensitivity and B_1-field characteristics etc. Thus, absolute-quantitative MRS is methodologically complex and difficult and has therefore only been applied in very few centers around the world. Here, we will discuss the physiological relevance and the *in vivo* application of cardiac ^{1}H-, ^{31}P and ^{23}Na-MRS for mouse and rat hearts.

^{1}H-MRS

Cardiac ^{1}H-MR spectroscopy detects several metabolites such as lactate, lipids, and creatine that can be used as indicators for the physiological condition of myocardial tissue. ^{1}H-MRS studies in human hearts have previously been reported [69,70,74–76], and this technique has also been applied *in vivo* to examine myocardial metabolism in dogs [65,77]. Of particular interest is the methyl-resonance of creatine at 3.02 ppm in proton spectra, which is commonly assigned to total creatine [both phosphorylated (PCr) and unphosphorylated creatine (Cr)]. Specifically, variations in creatine content have been shown to reflect tissue viability in the human heart [69].

We recently established cardiac ^{1}H-MRS in mouse *in vivo*, using a single voxel technique [78]. The signals of several cardiac metabolites originating from a 2 μl voxel, positioned in the interventricular septum of the mouse heart, were acquired within approximately 15–30 min using PRESS [79,80]. A ^{1}H-MR spectrum obtained from a normal mouse heart is shown in Figure 11a. Dedicated cardiac and respiratory gating (with steady-state maintenance) was crucial for the successful detection of the metabolite signals. The method was then applied to a murine model of guanidinoacetate *N*-methyltransferase (GAMT) deficiency [2] to show the absence of creatine in these hearts as indicated by the arrow in Figure 11b. This study demonstrated the feasibility of detecting and quantifying metabolites in the hearts of normal and genetically modified mice by ^{1}H-MRS *in vivo*. Applying this technique on multiple voxels or expanding it to chemical shift imaging (CSI) would be required to investigate heterogeneous alterations of cardiac metabolism. This is subject to future work, which will also involve the development of absolute quantification of metabolite concentrations in the mouse heart *in vivo* as outlined above.

^{31}P-MRS

^{31}P-MRS, which detects the signals of phosphocreatine (PCr), ATP, and inorganic phosphate allows for an investigation of cardiac energy metabolism. The intracellular pH can be calculated from the frequency shift between the resonances of PCr and inorganic phosphate. The ultimately relevant energetic parameter is the free energy change of ATP hydrolysis [81], given by:

$$[-\Delta G_{\mathrm{ATP}}\,(\mathrm{kJ/mol})] = \left|\Delta G^0 + RT \ln\left(\frac{[\mathrm{ADP}]\,[\mathrm{P_i}]}{[\mathrm{ATP}]}\right)\right|, \tag{4}$$

where $\Delta G^0 = -30.5$kJ/mol is the value for ΔG_{ATP} under standard conditions [82], R is the gas constant (8.3 J/mol K) and T the absolute temperature. The concentration of ADP, which is in the μM range and therefore below the sensitivity limit of MRS, is calculated indirectly from the creatine kinase reaction equilibrium according to:

$$[\mathrm{ADP}] = \frac{[\mathrm{ATP}]\,[\mathrm{Cr}]}{[\mathrm{PCr}]\,[H^+]\,K_{eq}}, \tag{5}$$

where $K_{eq} = 1.66 \cdot 10^9\,(\mathrm{mol}\,/\,\mathrm{l})^{-1}$ and [Cr] is the concentration of unphosphorylated creatine (i.e. the difference between [*total creatine*] and [PCr]). [PCr] can be determined from the ^{31}P-data and the total creatine content with quantitative ^{1}H-MRS. Thus, a combination of ^{1}H-MRS and ^{31}P-MRS would allow for a comprehensive and non-invasive determination of the myocardial energy state. However, creatine may only be partially MR visible [83] and this problem needs to be systematically evaluated.

Only few studies have reported on *in vivo* cardiac ^{31}P-MRS in mice. Omerovic *et al.* applied a single voxel method (ISIS, [84]) at 2.35 T using a double tuned ^{1}H-^{31}P-Helmholtz coil [85]. Metabolite signals of a voxel containing the left ventricle (voxel volume ≈120 μl) were detected within an experimental time of approximately 3 h. Weiss and co-workers applied a 1D chemical shift imaging technique (1D-CSI) at 4.7 T using a ^{31}P-surface coil [86–88]. The experimental time to collect the ^{31}P-data was ~34 min. Based on concentration measurements of total creatine and ATP and intracellular pH, obtained from perfused mouse heart experiments [89,90], they subsequently calculated the free energy change of normal mouse hearts from their ^{31}P-MRS data and obtained a value of approximately 60 kJ/mol. The application of this technique to GLUT4 null mice (i.e. mice lacking expression of the glucose transport protein GLUT4 (G4N) [91]) revealed a unique increase of 60% in the cardiac PCr/ATP ratio (2.4 vs. 1.5 in wild type controls) [88]. This higher ratio was due to an increased total creatine content in the heart of these mice. However, the concentration of ADP or ATP and the free energy reserve were unaltered [88]. Such an increase in creatine content has not been observed under any other circumstances, and the reasons for this remain to be elucidated.

This example illustrates the important role of ^{31}P-MRS in characterizing the cardiac energy metabolism of genetically modified mice non-invasively. Future work will focus on the implementation of absolute quantitative methods using CSI. SLOOP[2] as used in humans [66,67,92] is a method that achieves spatial localization and absolute quantitation, and could be a step forward towards the measurement of the high-energy phosphate concentrations in the hearts of rodents.

^{23}Na-MRS

The signal of sodium represents an intrinsic marker of myocardial viability: A cellular ion-pump maintains a transmembrane concentration gradient between the intracellular and the extracellular space (intracellular sodium concentration 10–15 mM; extracellular 145 mM [93]). This energy-consuming process is compromised during periods of ischemia, leading to elevated intracellular sodium concentrations. Furthermore, the extracellular space increases in scar tissue after myocardial infarction. Thus, changes in the detectable sodium signal may be an indicator of cell viability, as demonstrated in the isolated rat heart model (e. g. [93,94], see also Figure 12), or *in vivo* in rabbits [95], dogs [96,97], and humans [98,99].

However, the *in vivo* ^{23}Na signal has multiple T_2 components with approximately 30–40% of the total sodium signal having a T_2-value of around 1 ms. Thus, ultrashort echo times are essential in order to maximize the detectable sodium signal.

Based on dedicated localization techniques [100], Neuberger *et al.* were the first to report on the application of ^{23}Na 3D-CSI in normal and failing mouse hearts at 17.6 T [101]. They achieved a voxel size of 1 μl within an experimental time of approximately 1.5 h. This study was mainly limited by the size of the RF-coil and the gradient performance. Optimizing the hardware set-up further will likely benefit spatial resolution and SNR and therefore improve the value of this approach.

The studies mentioned above demonstrate the feasibility of cardiac MRS in mice. However, unlike cardiac MRI, this technique is far from a routine application in mice and rats. Hence, substantial future work is required to develop cardiac MRS into a tool that allows for a robust and reproducible investigation of physiological questions in normal and genetically modified animals. The trend

(See also Plate 72 on page XLVIII in the Color Plate Section.)

towards higher magnetic fields may be particularly beneficial for of cardiac MRS.

Vascular MRI

Genetically engineered mice are important for the study of atherosclerosis. Apolipoprotein E-knockout (ApoE$^{-/-}$) [102] or low-density lipoprotein receptor (LDLR$^{-/-}$) [103,104] deficient mice develop atherosclerotic lesions throughout the arterial tree, which resemble those found in humans. Lesion burdens in the aortic root [105], or in the brachiocephalic artery [106,107] are commonly investigated histologically as these are sites of early atherosclerosis development [108]. Although the histological methods have provided important insights into the development and the pathophysiology of atherosclerosis, the process of serial sectioning and histomorphometry is tissue-destructive, labor-intensive, limited to 2D analysis and precludes longitudinal investigation of the same animal. In particular, therapeutic interventions have been demonstrated to favorably alter plaque size and composition [109,110]. Therefore, the capability to investigate this serially in the same animal is highly desirable.

This can be achieved with high-resolution MRI. Although inferior in spatial resolution compared to histology, MRI is a valuable tool in investigating atherosclerosis in mice due to its non-invasive nature, inherent contrast mechanisms and 3D capability. However, contrast and spatial resolution must be maximized in order to resolve the ultra-small vascular structure with sufficient SNR and within acceptable/physiological imaging times. For example, it is worth noting that the thickness of a normal aortic wall in the mouse is less than 50 μm.

The first *in vivo* studies focused on the investigation of plaque development in the abdominal aorta and common iliac arteries of 36–84 weeks old apoE$^{-/-}$ mice due to reduced motional influence [111]. Slice-selective spin-echo sequences were employed with proton-density, T_2- and T_1-contrast. Total plaque area, quantified from the 2D MR-images correlated well with histology [111]. Choudhury *et al.* extended this work to 12–36 weeks old apoE$^{-/-}$ mice [112]. Studies of the aortic root or arch are technically more demanding due to substantial cardiac and respiratory motional influence. Only a few studies reported the quantification of atherosclerotic lesion size in the aortic root [113] and arch [114], or in the brachiocephalic artery [115] of mice. An example for detecting atherosclerotic plaque in mice by MRI together with the corresponding histopathological section is shown in Figure 13. All studies used spin echo sequences with black blood contrast, but only Hockings *et al.* applied it in three dimensions [115]. The achieved spatial resolution ranged between 49 × 98 × 300 μm [114] and 140 ×187 × 187 μm [115] before image interpolation, obtained within a scan time of approximately 30 min. This allowed for a correlation of the total plaque area as measured by MRI to the histological plaque area [114,115], as well as for monitoring the development of atherosclerotic plaque burden with age [113,115].

However, plaque composition is the more relevant parameter in humans as this rather than the size of the plaque determines the pathological consequences. Plaques in humans that feature a large lipid core and thin fibrous cap are susceptible to rupture provoking acute atherothrombotic events [116]. Furthermore, it has been shown in recent studies that lesions in the brachiocephalic artery of ApoE$^{-/-}$ mice have features of vulnerable plaque and, therefore, may better model human atherosclerotic

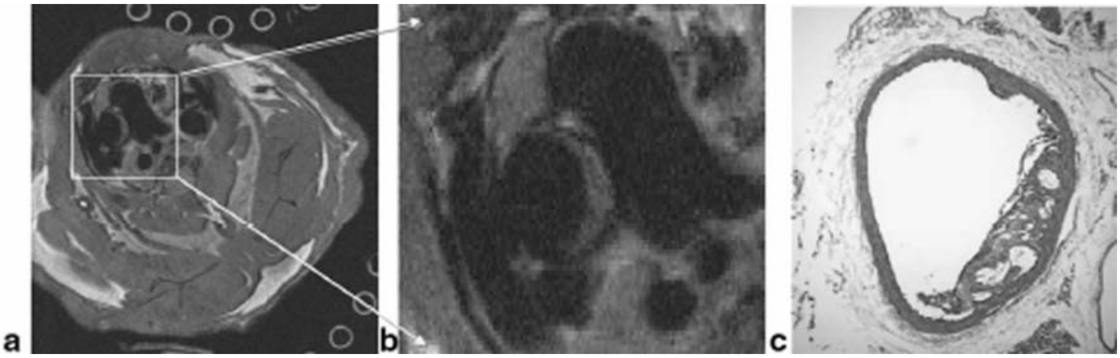

Fig. 13. Atherosclerotic plaque in apoE$^{-/-}$ mice *in vivo*. (a) Transverse MR image across the outflow tract of an apolipoprotein E knockout mouse. The ascending aorta is magnified in panel b and shows a close agreement in structure and wall area compared to the histological section (panel c). (From [114]). (See also Plate 73 on page XLVIII in the Color Plate Section.)

disease [106,107]. In order to distinguish between the different plaque components, multicontrast MR images are required. Combining the information from T_1-, T_2- and proton density (PD) weighted MR images, it has been possible to characterize both plaque anatomy and composition in experimental animals [117,118], *ex vivo* specimens [119–121], and in human carotid arteries [120,122] and aorta *in vivo* [123]. We have developed and applied high-resolution, multicontrast MRI techniques to quantify and classify atherosclerotic plaque in ApoE$^{-/-}$ mice *ex vivo* [124]. Specifically, we used a 3D multiecho sequence to differentiate and accurately quantify the volume of the plaque components in the aortic root and the brachiocephalic artery of ApoE$^{-/-}$ mice. MR images across the aortic arch and the brachiocephalic artery together with the corresponding histological sections are shown in Figure 14.

Although *in vivo* application of plaque imaging is the ultimate goal, at this moment *ex vivo* MRI, which has no motional influence, produces a level of spatial resolution for studies in mice, which may not be achievable *in vivo*. However, future *in vivo* applications may be facilitated by the use of targeted contrast agents (molecular imaging). For example Sirol *et al.* used a gadolinium-based contrast agent to enhance the contrast in lipid-rich plaques in rabbits [125]. Substantial future work will be required to develop this approach.

Conclusion and Future Perspective

In this chapter, we explained the importance of MR for a non-invasive characterization of the rodent hearts. Specifically, we demonstrated that the multiparametric MRI and MRS approach is crucial for a comprehensive analysis of normal and diseased hearts. The applications outlined here list the most prominent methods that are currently available for cardiovascular research in rodents. However, this list is far from complete. Other MR techniques, such as the assessment of perfusion in hearts of mice [126] and rats [127,128], or the investigation of foetal development in rodents by MR microscopy (see [129] for review) are also on the horizon.

In the future, a spread of this technology can be expected. The important role of MR as a phenotyping tool for rodent hearts has been widely recognized and this field is now rapidly expanding. New centers, dedicated to cardiac research in rodents, together with existing laboratories, will provide a platform for the routine application of MR in rodents.

Finally, the technological progress will also have a major impact on the future role of experimental CVMR. The development of new techniques will not only depend on advances in MR technology, such as parallel acquisition techniques (PAT) or simultaneous imaging of several specimen [130], but also on a multidisciplinary approach by physicists, chemists, physiologists, biologists, and cardiologists. This will be particularly necessary for the development of targeted contrast agents (molecular imaging) or in the rapidly growing field of stem cell research.

Acknowledgements

Our work was funded by Project Grants from the British Heart Foundation (BHF). We would like to acknowledge the important contributions from our colleagues and collaborators Prof. Kieran Clarke, Drs Paul Cassidy, Robin Choudhury, Dana Dawson, Craig Lygate, Martina McAteer, Matthew Robson, Damian Tyler, and Ms Karen Hulbert.

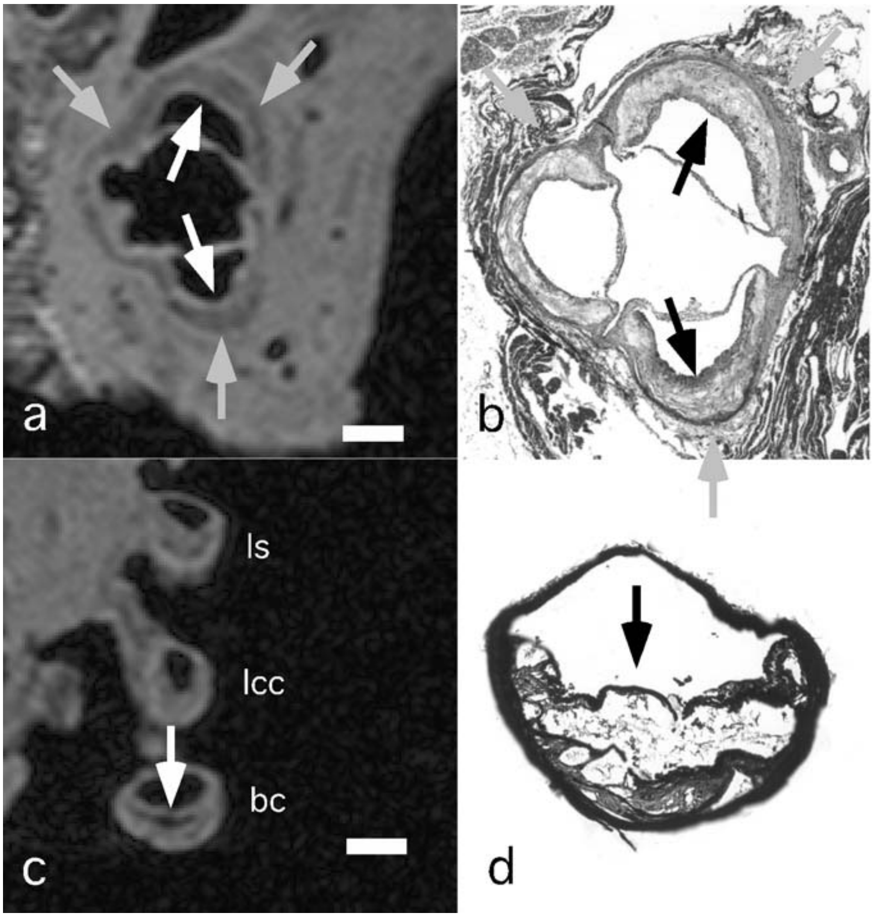

Fig. 14. Multicontrast MRI in apoE$^{-/-}$ mice *ex vivo*. Transverse MR images through the (a) aortic root and (c) through the head-and-neck vessels of an apolipoprotein E knockout mouse, obtained from the multiecho sequence. Four echoes with increasing echo times were acquired within one TR and subsequently averaged to provide a different degree of T_2-weighting for the various plaque components. The white arrows in panel a indicate the cellular layer that stained red in the histological section (black arrows in panel b). The green arrows illustrate the fibro-fatty plaque component (green stain in panel b). A lipid core is shown in the brachiocephalic artery (arrows in panels c and d). The voxel size of the MR images is 23 × 23 × 31 μm. Scale bar: 0.5 mm. Abbreviations: bc—right brachiocephalic; lcc—left common carotid and ls—left subclavian artery. (See also Plate 74 on page XLIX in the Color Plate Section.)

Application of Pharmacological MRI to Preclinical Drug Discovery and Development

Matthew D. Ireland and Steven C.R. Williams

Centre for Neuroimaging Sciences, Institute of Psychiatry, De Crespigny Park, Denmark Hill, London SE5 8AF, UK

Introduction

Several neuroimaging techniques now exist that provide ways of studying functional activity in the living brain. Having been widely used in the fields of cognitive and sensory neuroscience, functional neuroimaging has more recently been applied to investigating the way in which psychoactive agents affect brain activity. The non-invasive nature of functional magnetic resonance imaging (fMRI), coupled with its excellent spatial and temporal resolution and proven ability for investigating sensory, motor and cognitive functions in a non-invasive and repeatable way, have made it a particularly attractive technique for drug research, providing an insight into the functional effects of receptor activation *in vivo* in far greater detail than previously possible. This application of fMRI techniques to neuropharmacology, termed pharmacological MRI or phMRI [1], has been used to successfully demonstrate those regions of the brain that respond to a range of different psychoactive compounds. In addition to providing information concerning the regional specificity of drug action, the time course over which drugs act can also be established, as can the results of interactions between different compounds, and their central effects on cognition can be ascertained. By imaging activity throughout the entire brain, phMRI can determine the duration of drug-induced brain activity in all regions of interest with a temporal resolution down to several seconds, without the need for selective regional sampling. Despite its infancy, the use of phMRI has greatly expanded in recent years, having being used to examine the effects of CNS penetrating drugs in both humans and animals. Initial demonstrations that functional neuroimaging was able to detect drug-induced changes in brain activity in both humans [2–5] and animals [6–10], highlighted the enormous potential of such techniques for investigating drug action within the CNS. PhMRI is of particular interest to the pharmaceutical industry, with it being seen as having the potential to establish novel surrogate markers in animal disease models and provide early evidence of proof-of-concept for novel compounds, as well as helping characterize brain penetrability, pharmacokinetics, and the regionally specific actions of new drugs. By comparing existing "gold-standard" compounds with the patterns of neuronal activity induced by novel pharmaceutical agents, phMRI may help to establish potential efficacy, side effects, and therapeutic targets early in development. As phMRI is non-invasive and does not involve exposure to ionizing radiation, it can also be incorporated into longitudinal investigations of the neuroadaptive changes that occur during chronic treatment schedules that underlie the actions of many therapeutic agents.

Surrogate Markers of Neuronal Activity

Three of the main *in vivo* functional neuroimaging techniques currently in use are positron emission tomography (PET), single photon emission computed tomography (SPECT) and fMRI. None of these directly measure the output of active neurones, but instead rely on indirect measures of activity based upon the coupling of neuronal activity with glucose metabolism or cerebral blood flow [11]. Prior to the advent of *in vivo* functional imaging, measuring drug-induced changes in neuronal activity was mostly limited to *ex vivo* autoradiographic techniques. As the principal source of neuronal energy is glucose, measuring the cerebral metabolic rate of glucose utilization using 2-deoxyglucose (2-DG) autoradiography [12], provided one such way of detecting changes in brain metabolism. By using [^{14}C] labeled 2-DG, which becomes "metabolically trapped" inside active cells, rates of local energy metabolism in the brain can be calculated. However, being *ex vivo*, its use is restricted to single time point animal studies and temporal information concerning the duration of drug action is lost. PET studies using tracer quantities of ^{18}Flurodeoxyglucose (^{18}FDG), which like 2-DG is not fully metabolized but remains trapped inside active cells, are used in a similar fashion in both humans and animals to detect changes in altered cerebral glucose utilization *in vivo*. Whilst providing a direct measure of brain metabolism, the high costs and limited spatial and temporal resolution of PET due to sensitivity, positron traveling distances and detector arrangements (typically whole brain acquisitions take 30 s or longer), combined with restrictions on performing longitudinal

studies because of the radioactive and invasive nature of PET, limit broader applications of this technique. In particular, the more limited spatial resolution of PET has made it difficult to discriminate between structures within the brains of small animals typically used in preclinical research.

Hemodynamic-Based Functional Neuroimaging

Unlike 2-DG and ^{18}FDG PET, which measure changes in brain metabolism, fMRI and phMRI use hemodynamic measures based upon the coupling between regional cerebral blood flow (rCBF), regional cerebral blood volume (rCBV), and neuronal activity [13]. MRI provides several ways of indirectly measuring neuronal activity via changes in rCBF and rCBV. Although PET can localize regions of increased rCBF (and thus neuronal activity) using $H_2{}^{15}O$ tracers, like ^{18}FDG PET it also involves high scan costs and exposure to ionizing radiation. ^{99}Tc-HMPAO SPECT imaging can be used to measure rCBF at a lower cost than $H_2{}^{15}O$ PET, but has inferior anatomical resolution (typically not better than 5 mm voxel dimensions) and also involves exposure to radiation. The high spatial and temporal resolution of hemodynamic-based fMRI, coupled with its non-invasive and non-radioactive nature, have therefore resulted in it becoming the tool of choice for most *in vivo* functional neuroimaging.

MRI Measures of rCBF

MR images can be weighted to reflect rCBF by magnetically "tagging" arterial blood water and using it as a tracer. Such techniques are commonly referred to as arterial spin labeling (ASL), and include continuous ASL (CASL) [14] and flow-sensitive alternating inversion recovery (FAIR) [15]. These techniques require that two images are acquired, one with arterial spin labeling and one without, the differences between the images relating directly to rCBF. rCBF-weighted MRI predominantly reflects changes in tissues and capillaries rather than in veins, and has good functional specificity [16]. rCBF-weighted MRI has been used successfully for animal fMRI studies [17], but suffers from poor temporal resolution, requiring several minutes to produce a rCBF map, and is currently restricted to acquiring only a few slices at a time.

MRI Measures of rCBV

Measuring rCBV with MRI currently requires the use of an exogenous intravascular contrast agent with high magnetic susceptibility. Initial studies showed that administering a gadolinium conjugate, gadolinium dimeglumine (Gd-DTPA) allowed detection of signal changes of up to 40% in the visual cortex during photic stimulation by comparing images acquired without contrast agent to those acquired during the first pass of Gd-DTPA [18]. More recently, magnetic iron oxide nanoparticles (MIONs), that have a longer half-life than Gd-DTPA, have been successfully used to measure rCBF changes in animal fMRI experiments [16,19,20]. The long half-life of MIONs within the bloodstream allows a steady state concentration to be achieved, and as the concentration of contrast agent does not change with alterations in rCBF and O_2 consumption, only when rCBV increases during neuronal activity will the amount of contrast agent present locally rise, causing the MR signal to fall. As rCBV changes are closely related to rCBF, which is, in turn, specific to tissue, rCBV changes are largely reflective of alterations of blood flow within the parenchyma (close to the site of neuronal activity), as small vessels within tissue dilate more during stimulation than larger downstream vessels. The high magnetic susceptibility of contrast agents like MION have found wider use at lower magnetic field strengths [16], and the use of such agents has been particularly popular in animal phMRI, where concerns about the invasive nature and potential toxicity of administering exogenous contrast agents are slightly less. However, using contrast agents during phMRI experiments has raised concerns about the potential for saturating the liver enzymes upon which drug clearance is dependent, and this technique may not be suitable for extensive studies of drug pharmacokinetics. In addition, toxic side effects of many contrast agents may prevent longitudinal studies. CBV-based phMRI studies performed in animals may also be more difficult to translate to, or compare with, clinical investigations in humans, which usually employ BOLD-based techniques.

Blood Oxygen Level Dependent MRI

The most widely used fMRI technique to date is Blood Oxygen Level Dependent (BOLD) imaging [21]. BOLD signals result from changes in the level of paramagnetic deoxyhemoglobin that occur in areas of varying rCBF. As BOLD imaging requires no exogenous contrast agent, it has the advantage of being easy to perform, is completely non-invasive and provides high spatial and temporal resolution. As BOLD signals are sensitive to venous blood volume and vessel size, they are also detected in veins draining active areas of brain as well as in capillaries [22,23], and so may have a more limited spatial specificity than CBF- and CBV-based techniques. However, the sensitivity and specificity of BOLD signals can be enhanced by increasing the magnetic field strength and carefully optimizing the imaging pulse sequence parameters. The widespread and successful application of BOLD fMRI to human studies, the ease with which they can be performed, and the increasingly detailed understanding of the neurophysiological basis of the BOLD effect have ensured that most fMRI and phMRI experiments currently undertaken are based upon this approach.

MRI Origins of the BOLD Signal

Deoxyhemoglobin contains Fe^{2+} ions, which because of their unpaired outer electrons, exist in a high spin state, causing them to be paramagnetic. In contrast, oxyhemoglobin contains Fe atoms (having received electrons from oxygen atoms), giving them a low spin state and making them diamagnetic. Because hemoglobin is confined within blood vessels, gradient echo (GE) pulse sequences that are inherently sensitive to T_2* are able to detect changes in the relative concentrations of oxy- and deoxyhemoglobin [21,24]. In areas of active brain, an increase in glucose metabolism and O_2 extraction from blood is quickly followed by a larger fractional increase in rCBF, termed reactive hyperemia [13]. This increase in rCBF causes the net concentration of paramagnetic deoxyhemoglobin (which causes dephasing of spins and increases T_2* relaxation) to reduce, and the resulting T_2* BOLD signal correspondingly increases.

Some fMRI studies have reported detecting an initial decrease in T_2* signal within the first 1.5 s after the onset of stimulation which is associated with the initial increase in O_2 extraction that occurs prior to rCBF increasing. This signal decrease, termed the "initial dip," has been the cause of much excitement because of the potential gain in spatial specificity that imaging the initial dip (rather than the subsequent BOLD signal increase) would provide [25]. However, the failure of many laboratories to consistently observe the initial dip has made its existence controversial [26], and most fMRI studies rely on imaging the later, more robust BOLD signal increase. Imaging the initial dip is unlikely to be of practical value for most phMRI studies where stimulation periods following drug administration typically last for minutes or longer, rather than the transient neuronal activations more common to sensory and cognitive fMRI studies.

Physiological Origins of the BOLD Signal

Since the discovery of the BOLD effect and its application to functional neuroimaging, much work has been directed at understanding the hemodynamic and metabolic changes that underlie BOLD signals. A detailed understanding of the physiological basis for BOLD signals is particularly important for BOLD phMRI studies, where the drug under investigation may potentially interfere with the mechanisms that trigger BOLD signal changes. As neuronal activity rises, there is an increase in rCBF to provide additional O_2 and glucose to active areas of brain whilst facilitating the removal of waste metabolic products [13,27]. This increase in rCBF begins approximately 2.5 s after the increase in neuronal activity [28], the delay corresponding with the time taken for blood to travel from arteries to capillaries and veins. This increase in rCBF overcompensates for the extraction of O_2 from blood, causing the overall concentration of deoxyhemoglobin in local vessels to fall resulting in a corresponding rise in BOLD signal. In humans, BOLD signal increases typically reach a plateau between 4–12 s post-stimulation, depending on spatial location, type of stimulus, age and any existing pathology, and returns to baseline over a similar time period [29]. As BOLD signal changes arise from the susceptibility differences between deoxygenated blood and its surroundings, changes in venous blood volume (i.e. blood containing deoxyhemoglobin) and venous oxygenation levels are responsible for determining BOLD signal changes. Only venous blood volume (rather than total blood volume) affects BOLD signal, as arterial blood contains negligible amounts of deoxyhemoglobin [22]. Therefore, an increase in venous blood volume will decrease BOLD signal, whilst a decrease in venous deoxyhemoglobin concentration will increase BOLD signal.

rCBF, on which the BOLD response is dependent, increases in proportion to glucose consumption [27], which is in turn related to levels of synaptic activity [30,31]. Increased glucose utilization at active synapses may largely result from astrocytes recycling the neurotransmitter glutamate during excitatory neurotransmission, a process dependent on glycolysis producing energy from glucose but not requiring O_2. This may explain the proportional relationship between blood flow and glucose use in active brain areas (increased rCBF to supply extra glucose for glutamate recycling via glycolysis), and the discrepancy between blood flow and O_2 consumption: increased rCBF may supply glucose to astrocytes independent of blood oxygenation levels. However, recent investigations of the neurophysiological basis for BOLD signals have shown that metabolic and circulatory changes accompanying BOLD changes correlate closely with input into, and processing within areas of active brain, (i.e. synaptic activity), rather than reflecting spiking output of neurones [32]. Although spiking and synaptic processing may often be closely related, the amplitude of BOLD responses primarily reflect integration of pre- and post-synaptic processing [33]. Based on these findings, BOLD signal is therefore considered to reflect rCBF changes in the brain that are driven by synaptic signaling and related energy demands [11].

Although the basis for positive BOLD responses is now widely accepted, the process underlying sustained negative BOLD changes (as opposed to the initial dip) remain controversial. Several mechanisms for negative BOLD responses have been proposed, including reduced neuronal activity and O_2 extraction without a corresponding change in rCBF, a reduction in local rCBF independent of neuronal activity or a reduction in neuronal activity causing a controlled reduction in rCBF. Although the underlying mechanisms remain unknown, recent studies have shown that in human visual cortex, negative BOLD responses are temporally correlated with reductions in rCBF and local cortical O_2 consumption [34], suggesting that negative BOLD may reflect reductions in underlying neuronal activity.

BOLD signal changes can therefore be ascribed with confidence to changes in neuronal activity. However, the exact mechanisms whereby changes in neuronal activity mediate changes in rCBF remain unknown, with various possible mechanisms having been proposed. It is possible that lactate released from astrocytes during glycolysis might trigger an increase in rCBF, which would link cerebral hemodynamics closely with synaptic activity [35]. Alternatively, a quickly diffusible product of neuronal activity, e.g. nitric oxide, may be released during spiking activity, a possibility supported by reduced rCBF increases after administration of nitric oxide synthase inhibitors [36]. rCBF changes may also be directly coupled to changes in blood oxygenation levels, reacting to the "initial dip" in oxyhemoglobin levels [35].

Image Acquisition Strategies for Preclinical phMRI

Most human fMRI datasets are now acquired using Echo Planar Imaging (EPI) sequences, permitting the acquisition of an entire brain volume in 1–4 s. As animal phMRI studies usually involve measuring slowly evolving changes in signal that occur over tens of seconds or several minutes and persist for some time (depending on the route of drug administration and pharmacokinetic considerations), they do not require such rapid imaging. Therefore it is often preferable to use conventional GE (e.g. Fast Low Angle SHot, FLASH) or T_2-weighted spin echo (SE) sequences rather than EPI acquisitions. A single, whole brain volume is typically acquired over 40–120 s, with numerous volumes being continuously acquired for up to several hours, depending on the duration of drug action and anesthetic regime. Voxel size is much smaller than that in human imaging, typically being in the region of 0.5 mm in each plane, although smaller voxel sizes are possible at the cost of longer image acquisitions. To improve the spatial specificity of BOLD fMRI signals, it is desirable to minimize the venous contribution to BOLD signals, and this can be done by a careful choice of pulse sequence parameters. In particular, GE and SE pulse sequences differ in their relative sensitivities to venous blood vessels.

SE and GE BOLD Imaging

BOLD signal from deoxyhemoglobin has intravascular (IV) and extravascular (EV) components from both small and large vessels [22,37], and the exchange of water molecules between these compartments is slow (greater than 500 ms) in comparison to the imaging time (TE less than 100 ms). MR signals arising from each compartment can therefore be considered separately. EV effects result from the dephasing of spins induced by field inhomogeneities around vessels containing paramagnetic deoxyhemoglobin, creating a magnetic field gradient which is more spatially extensive for larger vessels (i.e. veins). The IV component exists because the deoxyhemoglobin content influences the T_2 and T_2* of blood, as well as the surrounding tissue. Both IV and EV effects contribute to GE BOLD fMRI signals, but SE pulse sequences are able to reduce the EV signal arising from large vessels. Because water molecules are able to diffuse within the small areas of susceptibility around capillaries during imaging (TE typically being less than 50 ms), and have a large net displacement, their effects are "dynamically averaged" during a TE and produce no net phase change. However, water molecules can only diffuse within a small part of the greater area of susceptibility surrounding larger vessels, having a smaller net displacement, and so are "locally averaged" during each TE [38]. This allows the EV dephasing effects around large diameter vessels to be refocused by a 180° RF pulse during a SE sequence, whilst the dephasing around smaller diameter vessels remains unaffected due to dynamic averaging. Such refocusing of dephasing around large diameter vessels means that SE BOLD sequences minimize the EV contribution of large venous vessels (whilst continuing to be sensitive to the IV contribution of all vessels and the EV effects of capillaries) and so maximize spatial specificity [39]. GE BOLD signals consists of the IV and EV contribution of all venous vessels, and are therefore more susceptible to the effects of veins draining areas of activated tissue. The removal of EV effects means SE sequences are less sensitive and have lower maximum signal changes than GE sequences, as well as having a lower temporal resolution due to longer imaging times [39]. For these reasons, GE BOLD is often used in preference to SE BOLD because of its higher sensitivity and temporal resolution, and lower RF power deposition within tissues, although BOLD-based animal phMRI studies have been successfully performed using both GE [40,41] and SE [42] approaches.

Effects of Magnetic Field Strength

The strength of the static magnetic field has important effects on the BOLD signal detected by GE sequences. The intensity of GE BOLD signal increases with field strength [43], making fMRI studies at higher fields increasingly popular. In addition, the field gradient around capillaries is greater at higher static magnetic fields, making BOLD signal more closely coupled to neuronal activity [44]. However, GE imaging, particularly non-EPI, FLASH-based sequences are susceptible to inflow effects caused by fresh (fully recovered) spins in blood moving into regions excited under T_1 saturation conditions that occur during rapid imaging. These effects are more apparent at short TR values and large flip angles [39] and can be minimized by reducing flip angles and increasing TR.

Considerations Particular to phMRI

The nature of the BOLD signal as a secondary marker of neuronal activity, combined with continuing uncertainties surrounding the way in which neuronal activity, rCBF, and rCBV are coupled together, pose particular problems when planning and interpreting the results of phMRI experiments. Due consideration must be given to the effects that drugs may have on the cerebrovasculature and those mechanisms that give rise to the BOLD signal. It is possible that a drug of interest may act directly on receptors located on the cerebral blood vessels and so alter rCBF independently of any changes in underlying neuronal activity. Alternatively, the neurochemical processes that couple neuronal activity with blood flow may become disrupted. As animals are anesthetized and unconscious for the duration of the experiment, careful monitoring is needed to ensure maintenance of stable physiological parameters. Typically, heart rate, blood pressure, respiration, and temperature are recorded, and animals may be artificially ventilated to maintain stable respiratory and blood gases. It has previously been demonstrated that BOLD signals can be altered by increasing $paCO_2$ levels during CO_2 inhalation [45], and that spontaneous fluctuations in end tidal CO_2 correlate with changes in BOLD signal in both gray and white matter in human volunteers [46]. Elevated $paCO_2$ levels cause cerebral blood vessels to dilate, producing a global increase in BOLD signal that can eventually rise to such an extent that blood vessels are no longer able to dilate in response to increased neuronal activity. Administering heroin to spontaneously breathing rats has been shown to cause a global decrease in BOLD signal, thought to result from the respiratory depression induced by heroin [47]. However, when is given to rats being artificially respirated, BOLD signal increases are restricted to those brain regions containing a high density of μ opioid receptors [47]. This effectively demonstrates how the systemic effects of a drug can subsume any neuronally induced changes in BOLD signal. For this reason, the monitoring and regulation of respiration and $paCO_2$ levels during animal fMRI and phMRI experiments are crucial to ensuring the validity of observed BOLD signal changes.

Many experimental drugs also induce changes in systemic blood pressure that may alter CBF and thus BOLD signal. Although small, gradual reductions in blood pressure of the order of approximately 1 mmHg/min are known to have no significant effect on BOLD signal [48], when the blood pressure of rats is rapidly and significantly reduced by controlled withdrawal of arterial blood, a heterogeneous pattern of statistically significant reductions in BOLD signal is observed within the brain that follows the same time course as the decrease in blood pressure [49]. Thus any large, rapid fluctuations in blood pressure that follow drug administration represent a potentially serious confound for phMRI, and since the patterns of BOLD signal change induced by such alterations in blood pressure are not globally uniform, assessing and eliminating these effects may prove difficult. The close monitoring of blood pressure and subsequent testing to ensure the time course of blood pressure and BOLD signal changes are not correlated are crucial to ensure that valid inferences are made from phMRI experiments.

During human phMRI studies, the potential confounding effects of the drug on neurovascular coupling can be assessed by examining the effects of a drug on the BOLD response to well-characterized cognitive or sensory tasks. For example, a finger-tapping task has been used to demonstrate that the dopaminergic agent methylphenidate does not alter baseline signal or task-induced BOLD signal changes in the motor cortex, and so provide assurance that any experimentally-induced changes in cortical BOLD signal resulting form methylphenidate administration are not due to any direct systemic or vascular effects of the drug [50]. The opportunities for using similar approaches are more limited in phMRI experiments using rodents and other experimental animals. Although it is possible to examine modulations of the cortical BOLD response to basic sensory stimuli such as forepaw stimulations, those brain regions expected to respond to such a stimulus may not contain a high density of receptors for the neurotransmitter system of interest, and cerebral blood vessels in such regions might not necessarily be affected by the administered compound. It is therefore particularly desirable that as much physiological information as possible is collected simultaneously during imaging, with variables such as expired CO_2 levels being controlled by artificial ventilation whenever feasible. In addition, it is important to have some appreciation of the known or potential effects that a drug may have on the cerebrovasculature. The possibility of non-specific changes in BOLD signal during phMRI experiments has meant that collecting additional measures of brain activity such as those provided by electrophysiology or microdialysis are becoming increasingly important, particularly when validating the results of initial phMRI experiments involving previously untested drugs. It may also be desirable to use alternative imaging sequences before and after drug administration to assess any generalized changes in CBV and CBF to further validate the exact nature of any observed changes in BOLD signal, particularly when potentially confounding changes in physiological parameters are also observed.

Validating phMRI Experiments

One of the first studies to demonstrate the usefulness of BOLD imaging for measuring the effects of dopaminergic compounds in the brain of rats was performed in 1997 by a group at the Massachusetts General Hospital [7]. By examining the BOLD response to amphetamine and the radiolabeled dopamine transporter antagonist CFT, and additionally using PET and microdialysis to measure dopamine receptor binding and dopamine release, BOLD signal changes were shown to correspond with PET measures of dopamine transporter levels, and the time course of BOLD signal and dopamine release were found to closely correlate, and be temporally unrelated to changes in $paCO_2$, heart rate, or blood pressure. In addition, animals were prepared with unilateral 6-hydrodydopamine lesions to the striatum, and the extent of rotational behavior demonstrated by individual animals in behavioral studies (which is related to dopamine release) was shown to correlate with the magnitude of the observed BOLD signal response. By combining phMRI, PET, microdialysis and behavioral measures, this study provided an early validation of the use of BOLD fMRI to study the mechanism of drug action and demonstrated the way in which effective control conditions and study design can be used to overcome the potential confounds associated with phMRI.

The well-described effects of cocaine and related compounds on heart rate and blood pressure, and the potentially detrimental effects of such systemic changes on phMRI measures, have made validating the results of phMRI studies using cocaine important in testing the robustness of the phMRI technique [7,9]. The possibility of using phMRI to investigate drugs that have cardiovascular side effects was effectively demonstrated by a study comparing the effects of cocaine and its non brain-penetrant quaternary analog, cocaine methiodide [51]. Whilst both compounds increased heart rate and blood pressure, cocaine methiodide produced only small, scattered, and transient increases in brain BOLD signal, independent of drug dose. In contrast, cocaine increased BOLD signal within limbic brain regions in a dose-dependent fashion, as well as increasing systemic blood pressure. The effects of cocaine on blood pressure therefore appear to have had little confounding effect on drug-induced BOLD signal within the brain. Recent studies have continued to use cocaine as a prototype for validating phMRI. Experiments combining CBV-based phMRI measures and microdialysis have shown that dopamine release and rCBV changes have different temporal profiles in the striatum and medial prefrontal cortex, and that observed increases in rCBV within the motor cortex are independent of any changes in dopamine release [52]. This effectively demonstrates that the phMRI response to cocaine in these regions cannot be a direct result of increased levels of dopamine release acting directly on cerebral blood vessels, but is instead likely be a true reflection of underlying changes in neuronal activity. Combining phMRI with additional measures such as microdialysis not only helps to prove that phMRI experiments are indeed detecting changes in brain activity, but are also of value in helping to understand the relationship between phMRI responses to drugs and changes within individual neurotransmitter systems and brain circuits. In another recent study, the confounding peripheral effects of cocaine were circumvented by injecting the drug directly into the brain of awake animals during phMRI experiments [53]. The resulting increases in BOLD signal within limbic and cortical brain regions, combined with an absence of concomitant changes in heart rate or blood pressure, not only support the findings of previous phMRI studies using cocaine as being genuine reflections of changes in neuronal activity, but also demonstrate the feasibility of using direct injection techniques with phMRI measures to overcome either the confounding peripheral effects of drugs under investigation, or problems with brain penetrability. However, further difficulties with this approach may arise when changes in intraventricular signal arise from injection of fluid into the brain rather than from activity-dependent changes in BOLD signal.

It is also possible to combine the *in vivo* measures of drug-induced neuronal activity provided by phMRI with *ex vivo* measures. For example, variations in the phMRI response to diazepam in the frontal cortex of high and low anxiety behavior rats has been shown to correspond with differences in the number of neurones expressing the immediate early gene *c-fos* in animals with different phenotypes following exposure to environmental stressors [54]. Combining phMRI with other *in vivo* and *ex vivo* techniques such as microdialysis, autoradiography, and measures of gene expression is likely to become increasingly common as phMRI experiments become more sophisticated and are required to provide information concerning not only those brain regions that respond to a given drug, but also the mechanisms underlying the observed response.

Effects of Anesthesia

Animal fMRI experiments, especially those involving rodents, usually require the use of an anesthetic to immobilize the animal for the duration of the study. Whilst anesthesia minimizes motion artifacts during imaging and limits the confounding effects of stress caused by the scanning environment, the effect of anesthesia on normal neuronal functioning is clearly a problem. Whereas blood pressure and $paCO_2$ levels can be monitored and to some extent controlled for, the effects of anesthesia cannot be easily controlled. Although counter-intuitive that neuronal responses should remain detectable in an anesthetized state, responses to both sensory and pharmacological challenges have now been repeatedly demonstrated in anesthetized animals. However, anesthetic agents are known to affect both cerebral blood flow [55] and cerebral metabolism [56]. As such, careful consideration must be given to the choice of anesthetic before undertaking such studies. Animal fMRI studies have been conducted using a variety of anesthetic agents, ranging from inhalation anesthetics like halothane and isoflurane [7,32] to injectable anesthetics like α-chloralose [57] and urethane [40]. As experience of using different anesthetic agents in fMRI and phMRI has been gained, attempts have been made at understanding whether any of the effects on particular neurotransmitter systems are anesthetic-specific, and would make particular anesthetics more or less suited to certain applications such as sensory fMRI or phMRI. The largely unknown mechanism of action of most anesthetic agents, combined with a lack of information with regards to those neurotransmitter systems affected by different agents, has made predicting the effects an anesthetic may have on the outcome of a phMRI experiment difficult. In addition, many anesthetics may also act in a species-specific fashion.

Injectable Anesthetics

One of the most widely used anesthetics in animal fMRI is the injectable agent α-chloralose. Its popularity is largely due to it being thought to preserve functional metabolic coupling within the cortex and maintain stable cardiovascular parameters [58], whilst causing only minimal depression of autonomic functioning [59,60]. α-chloralose also permits greater increases in rCBF within the sensory cortex in response to peripheral sensory stimulation than barbiturate or halothane anesthesia [61]. Although α-chloralose has been widely used and cited within literature as a suitable anesthetic for *in vivo* studies on brain functioning and rCBF, it is known to have depressive effects of animal physiology, e.g. respiratory depression with prolonged anesthesia [59], and it may be desirable to use artificial respiration when using α-chloralose to prevent respiratory depression and associated confounding changes in $paCO_2$ levels. The popularity of α-chloralose in early sensory animal fMRI studies [57], combined with the long-lasting and stable anesthetic state which it produces, have made it a natural choice for many phMRI investigations. In our laboratory, α-chloralose has been successfully applied to phMRI studies of dopamine D_2/D_3 receptors agonists, and it has also been used to examine the effects of the D_2 receptor antagonist sulpiride [62], as well as the NMDA receptor antagonist MK-801 and the 5-HT_2 receptor agonist mCPP [63]. Some controversy exists as to the suitability of α-chloralose for phMRI studies of the dopamine system as it may suppress dopamine release [64] and has been shown to prevent CBV responses to the indirect dopamine agonist cocaine which can be detected under halothane anesthesia [9]. Another injectable anesthetic, urethane, has also been exploited for animal phMRI studies because of its ease of use and long-lasting and stable anesthetic state, and has been successfully applied to studying precipitated withdrawal from both opiate [40] and nicotine [41] dependent states, as well as the effects of tolerance following heroin self-administration [65]. Chloral hydrate, which like urethane is administered intraperitoneally, has also been used in phMRI experiments to investigate the cannabinoid agonist HU201 [42].

Inhalation Anesthetics

Inhalation anesthetics like halothane and isoflurane have also been successfully applied to animal fMRI and phMRI studies. Halothane has proved particularly popular for studying the effects of dopaminergic ligands, having been used to examine the effects of cocaine and related ligands in several different laboratories, with comparable changes in BOLD or rCBV being reported within limbic and striatal regions as well as the frontal cortex [7,9,52,66,67]. In a similar fashion, isoflurane has also been used in studies of the $GABA_A$ antagonist bicuculline in mice [68]. A comparison of the effects of apomorphine in awake rhesus monkeys with those anesthetized using isoflurane showed that whilst BOLD signal increases were observed throughout the basal ganglia in awake animals, they were restricted to the substantia nigra in anesthetized animals, where the magnitude of signal increase was considerably diminished compared to the awake condition [69]. Halothane has similarly been shown to diminish the BOLD phMRI response evoked by the NMDA receptor antagonist MK801 when compared with a combination of fentanyl/fluanisone/midazolam injectable anesthetic agents [6]. Such confounding changes in CBF are in addition to the effects the anesthetic may have on basal and evoked neuronal activity. Studies in our laboratory have shown that whilst activation of the sensory cortex is easily and repeatedly observed following electrical stimulation of the rat forepaw using α-chloralose, such responses are completely abolished when using even minimum levels of isoflurane. This reduced ability to detect changes in BOLD signal under isoflurane anesthesia is likely to be caused by the effects of isoflurane on the regulation of rCBF. Isoflurane dose-dependently increases rCBF in most brain structures in Sprague Dawley rats [70,71,72], with some regions showing an increase in local rCBF of up to 238% [70]. Perfusion-weighted MRI has shown that isoflurane not only dose-dependently increases rCBF in rats, but also suppresses cerebrovascular reactivity and reduces the magnitude of both rCBF and BOLD signal increases to hypercapnia following CO_2 challenge [73]. In addition, isoflurane has also been shown to blunt the fMRI response to both noxious and non-noxious somatosensory stimuli [74]. As BOLD signals depend on the modulation of rCBF within active areas of brain [21,13], any increase in rCBF that is unrelated to changes in neuronal activity may confound both the evolution of the BOLD response (if rCBF is already raised it may not need to increase further to supply active brain regions) and the ability for any increases to be detected using fMRI (by reducing vascular reserve). Careful consideration needs to be given to the choice of anesthetic prior to beginning a phMRI study, with bench testing needed to ensure that the chosen anesthetic agent is used at the minimum ethically acceptable level. Where possible, it should also be ascertained that the neuronal systems of interest remain responsive under the chosen anesthetic using measures like microdialysis or electrophysiology. Cross correlation of phMRI results using different anesthetic agents is also important when validating animal phMRI studies, but given constraints on time and resources, repeating phMRI experiments using different anesthetics may not always be a practical option.

PhMRI in Awake Animals

Although to date most animal phMRI studies have been performed under anesthesia, several groups have demonstrated the possibility of imaging awake animals following a period of training. This approach was successfully applied using rhesus monkeys to examine the effects of the non-specific dopamine agonist apomorphine and showed the severe blunting of the phMRI signal that occurs when using isoflurane [69]. Conscious rabbits have also been trained and adapted to the scanning environment and have been used to examine the effects of the dopamine antagonist sulpiride [75]. Several studies have reported the results of phMRI experiments in conscious rats, where animals are restrained, often following the surgical attachment of bolts to the skull to allow secure positioning within an MR-compatible headframe. Such imaging of conscious rats has been used to assess the effects of interaction between the dopamine D_2 receptor agonist bromocriptine and the D_2 receptor antagonist haloperidol [8], determine the sites of action of the endogenous cannabinoid anandamide [76] and most recently, to examine the effects of intracerebroventricular cocaine administration [53]. Although imaging awake animals has clear benefits in terms of avoiding the confounding effects of anesthesia on drug-induced brain activity, other factors, including greater movement artifacts, training time, cost and ethical implications have precluded a more widespread application of this approach. In addition, accounting for the confounding effects of stress during the imaging experiment may prove as difficult as identifying the likely effects of anesthesia on drug-induced neuronal activity.

Data Analysis

Considerable effort has been devoted over recent years to developing standardized techniques for the analysis of BOLD fMRI data. One of the most widely used analysis tools is Statistical Parametric Mapping or SPM (http://www.fil.ion.ucl.ac.uk/spm), originally developed for the analysis of human PET and subsequently fMRI studies which we have now extended to animal fMRI and phMRI studies [40,41]. The use of SPM and similar standardized approaches for data analysis is becoming increasingly popular as animal fMRI and phMRI techniques become more widespread, replacing more parochial data analysis tools that may lack the statistical flexibility and support of more widely used software that has been validated within the peer-reviewed literature. Using freely available software like SPM for data analysis not only enhances the statistical rigor of analytical methodology but also allows the results from different experiments and laboratories to be more easily compared and reproduced.

Image Pre-processing

Data analysis software packages currently available, like SPM, AFNI (http://afni.nimh.nih.gov/afni), and FSL (http://www.fmrib.ox.ac.uk/fsl), now have a common approach to most image pre-processing steps and subsequent statistical analysis. Rather than relying on results obtained from individual subjects, typically data from groups of subjects are analyzed together in order to both improve statistical power and make inferences about the generic response of the population under investigation. Prior to statistical analysis, fMRI data must undergo considerable pre-processing. To perform voxel-based analysis, data must be placed in the same anatomical frame of reference, and the first stage in achieving this is spatial realignment. Subject movement during imaging causes a change in voxel signal intensity unrelated to experimental conditions, which represents a potential confound in data analysis. Even sub-voxel movements introduce unmodeled noise in the data, causing artifactual "activations" at tissue edges and reducing signal-to-noise within images. To minimize these effects, a realignment algorithm moves images to the same common space, ensuring that a single voxel will represent the signal intensity from tissue in the same position throughout the experimental time series. To perform group analysis of data from different subjects, variations in brain architecture between subjects must also be accounted for before comparisons of similar brain regions can be made. Most fMRI analysis software transform each subject's brain into a common reference space in order to minimize neuroanatomical differences between subjects prior to analysis. Within SPM99, this process warps images to a standard brain template by applying a 12 parameter affine transformation to determine the minimum deformation needed to minimize differences in global shape between the subject's brain and the template, whilst attempting to preserve spatial relationships between intracerebral structures [77,78]. Many of the difficulties associated with coregistering the brain anatomy between different subjects, a step crucial to allowing the implementation of group statistics, are minimized when using in-bred, age, and weight matched animals in preclinical investigations. The final pre-processing step involves using Gaussian filter kernels to spatially smooth data, which effectively lowers the resolution compared to that of the "raw" data. Gaussian smoothing improves the signal-to-noise ratio of data (a measure of the size of the signal of interest compared to the random background noise which is present without stimulation), and aids the detection of "activations" which are similar in size to the smoothing kernel (particularly important if high resolution data are acquired and widespread regions of activation are anticipated). When performing group analysis with data from multiple subjects, smoothing also helps to remove any remaining differences in neuroanatomy between subjects after spatial normalization and increases the likelihood of detecting activations across groups of subjects. Most importantly, SPM99 and other analysis packages involve an implementation of Gaussian Random Field theory to control for the effects of making multiple comparisons during statistical analysis, and spatial smoothing data ensures the validity of subsequent statistical inferences.

Global Effects and Fluctuating Baseline Signal Intensity

Analysis of BOLD fMRI data to produce statistical maps of changes in neuronal activity is non-quantitative, involving the comparison of experimentally induced changes to a known baseline. The baseline MRI signal however fluctuates over time, even in the absence of experimental manipulation, due to factors such as those originating in hardware (scanner drift), physiological changes like variations in the level of anesthesia, $paCO_2$, or blood pressure which affect global perfusion levels, movements from respiration and heartbeat [79], and potential creation of intermittent imaging artifacts [80,81]. The presence of such fluctuations in baseline signal intensity presents a problem when analyzing data, and may be particularly pertinent to phMRI where the physiological effects of a drug may produce substantial global signal changes. Unlike signal changes resulting from "activations," baseline signal fluctuations have no regional specificity, being termed global confounds. Over the course of an experiment, such global effects may be larger than any experimentally induced BOLD signal change and measures need to be taken to estimate and account for such effects when analyzing fMRI data. To try and remove or account for global effects, they are assumed to be independent of experimental manipulations, with regionally specific, experimentally induced changes in signal intensity considered as being superimposed upon global changes. Typically, global effects are estimated from the temporal profile of all intracerebral voxels, each of which is then scaled to a common value (proportional scaling) to produce a flat baseline mean signal intensity value. Alternatively, the global signal intensity may be included as a covariate of no interest within the General Linear Model analysis in addition to, or instead of, proportional scaling, an approach known as ANCOVA [80]. These methods of controlling for global effects become problematic when experimentally-induced signal changes are large, and there is a resulting correlation between global signal changes and localized signal changes of interest. Specifically, scaling of data containing large, experimentally-induced signal increases may produce artifactual signal decreases in areas of the brain which did not previously have any change in signal intensity and vice versa. Where regional, experimentally-induced signal intensity changes are large, it may be preferable to omit proportional scaling and instead look at absolute changes in signal intensity, providing regional changes large enough to be apparent over and above a fluctuating baseline. The inclusion of global signal change as a covariate of no interest within the statistical model (ANCOVA) when it does not co-vary with the experimental manipulation has only quantitative effects on the resultant statistical maps, increasing the significance of observed changes by reducing error within the model. However, when such a covariate correlates with the experimental model (and so becomes a confound rather than a nuisance variable), this may change the interpretation of results in both a qualitative (changing the sign of relationships) and quantitative (changing the significance of relationships) fashion. Alternative measures of baseline signal intensity can also be derived from regions known to be unaffected by experimental conditions e.g. muscle [81] or white matter, which are then used to estimate baseline fluctuations and either scale mean signal intensity accordingly or provide an estimate of global effects for inclusion within GLM analysis. Estimating and controlling for global changes in signal intensity is equally important for CBV-based phMRI studies, where clearance and/or recirculation of the exogenous contract agent over the course of the experiment can produce large global signal intensity fluctuations.

Statistical Analysis

Statistical analysis is performed to identify those voxels responding to experimental manipulation. Typically, univariate analysis is used involving the time series of each voxel being analyzed independently from all others (voxel by voxel analysis), as opposed to multivariate analysis, where spatial relationships within the data are also considered. SPM99 is a univariate model-based analysis: a model of the expected response (e.g. response to periods of stimulation, concentration of pharmacological agent, or known behavioral covariate) is fitted to the data, and if a good fit between the model and data results then changes within the data are considered likely to result from the experimental manipulation [77]. Such a test is performed independently at each voxel. This is alternatively known as analysis of covariance or multiple regression and is based on the General Linear Model. The final output from such an analysis is a statistical map of the group BOLD signal response, with each voxel representing the statistical significance of a particular region under the hypothesis being tested.

Modeling the BOLD Response to Drugs

Data analysis packages based upon the General Linear Model require that changes within the data be measured and tested against a model of the expected BOLD signal response to the experimental condition. In conventional human fMRI studies, an experimental stimulus or cognitive task is often presented at set intervals and this serves as an initial, idealized model for analysis. Some human phMRI studies use a variation on this approach, where a drug is administered and the effects on patterns of activation occurring in response to a repeated stimulus or task are measured. Unless the purpose of the experiment is to investigate drug-induced modulations of a basic sensory stimulus, for most animal phMRI studies this approach is not feasible. Instead, investigations are aimed at assessing the direct consequences of drug administration on baseline patterns of neuronal activity. Whilst this approach is difficult in humans due to problems in creating a “behavioral clamp” which controls the basal level of brain activity over the course of the experiment, it is less of a concern when using anesthetized animals. However, difficulties arise when choosing a suitable model of the expected drug response for data analysis and several approaches exist for producing such models. The most basic of these involves comparing all pre-injection images with those collected after the drug has been administered. This is most suitable for compounds known to have a rapid onset of action and the effects of which persist for the duration of the experiment. Drawbacks of using a simple “off/on” model are that any regions of the brain that show rapid or transient changes in activity may remain undetected as detailed temporal information is lost. In addition, any slowly occurring linear changes within the data (such as scanner drift, or “colored,” physiological noise) may correlate well with a simple “off/on model” and produce signal changes within the data that closely correlate with the model, producing spurious patterns of activation and deactivation. Using drugs with a short duration of action allows repeated injections in a randomized fashion, but may cause problems in terms of diminished effect of drug with repeated challenges and possible confounding physiological changes associated with i.v. drug administration.

A more sophisticated approach to phMRI data analysis involves using known pharmacokinetic or pharmacodynamic parameters against which to model drug-induced changes in BOLD signal. The use of pharmacokinetic models was demonstrated using a Waveform Analysis Protocol (WAP) based on single dose pharmacokinetics to examine the acute effect of nicotine in humans [82]. By producing an idealized BOLD signal response to nicotine based upon its known pharmacokinetic profile, this WAP was applied to the imaging data and comparisons made between the time and rate of onset of drug action, time-to-peak, and duration of response to determine whether observed changes following drug administration match with the pharmacokinetics of nicotine. This approach assumes that the concentration of drug within the peripheral circulation will be equivalent to that in the brain (which is true for short-acting, highly lipophilic compounds such as cocaine and nicotine), and that drug-induced changes in brain activity will reflect drug concentration within the brain. One of the major advantages of this approach compared to simple “off/on” comparisons is that the gradual drift in MRI signal over time commonly observed during fMRI experiments will not correlate with the modeled response as it will be both too slow and will not rise then fall over time, unlike the blood concentration of a short-acting drug. This approach has been developed further by combining a pharmacokinetic model of the short-acting analgesic remifentanil with a repeated, painful stimulus to examine pain processing within the brains of human volunteers [83]. Although to date pharmacokinetic-based approaches to phMRI analysis have been mostly been performed in humans, this method is equally valid for animal phMRI studies, where a lack of cognitive or sensory paradigms that can be used to assess drug-induced modulations in brain activity make pharmacokinetic modeling particularly attractive.

In a similar way, pharmacodynamic changes such as the effects a drug has on behavioral measures like locomotor activity, or alternatively known changes in neurotransmitter release, can also be used as models for data analysis. This approach can be particularly useful where a drug has more than one effect with differing time courses, and can help identify those areas of the brain that are responsible for mediating such changes. As it is likely that the temporal response between brain regions will differ, using a variety of different models helps ensure that as much detailed information as possible concerning regionally specific drug effects is extracted from a given dataset. Our laboratory has pioneered this approach to phMRI data analysis for experiments designed to investigate the mechanism of action of dopamine agonists in the rat brain.

Using Dopamine Receptor Agonists as Prototypical Agents for Animal phMRI

We have examined BOLD responses to the D_2/D_3 receptor agonist quinelorane as a means of both further characterizing the mechanisms of action of this particular compound, and also as a means of evoking a response in phMRI experiments in order to optimize, refine, and better understand the phMRI technique itself. Although a variety of agents exist that are agonists at D_2-like receptors, quinelorane is highly potent at both D_2 and D_3 receptors and has a very low affinity for other dopamine and non-dopamine receptors [84–89]. The highly potent and selective nature of quinelorane, combined with its ability to evoke behavioral responses at sub-milligram doses, minimize the likelihood of non-neuronal or confounding drug effects occurring that may become evident when higher doses of less specific agents are used, and as such makes it an attractive agent for use in phMRI studies.

Imaging Protocol

A typical phMRI experiment involves examining the BOLD response to a 30 μg/kg dose of quinelorane, which in awake animals induces a biphasic change in locomotor activity that persists for several hours. Prior to imaging, rats are anesthetized with isoflurane to facilitate the cannulation of a tail vein, after which anesthesia is switched to intravenous α-chloralose at a dose of 60 mg/kg/h. Animals are then imaged using a conventional FLASH gradient echo sequence, with quinelorane being administered by subcutaneous injection half way through the imaging experiment. Heart rate, blood pressure, and temperature are all continuously monitored to ensure animals remain physiologically stable during the experiment and that there are no significant effects of drug administration on any measured physiological parameters. Subsequently, images are then analyzed using SPM99 software: following image realignment and spatial normalization to a customized rat brain template, several different strategies can then be applied to subsequent statistical analysis.

Data Analysis

We present data here that illustrates the BOLD phMRI response to 30 μg/kg quinelorane as determined using three different approaches to data analysis. In the first example, a simple comparison between pre- and post-injection scans (“off/on” model) was used to assess the main effect of the drug, an approach that has been used several times previously for analyzing phMRI data [4,90]. As the behavioral effects of quinelorane persist for longer than the duration of the imaging experiment, a comparison of pre- and post-injection scans is a suitable method of assessing the BOLD signal change evoked by this particular compound. A second approach involved producing a pharmacokinetic model of the temporal dynamics of quinelorane blood concentration (Figure 2). As quinelorane is lipophilic, with good brain penetrability [91,92], this approach assumes a good correlation between blood and brain drug levels and that BOLD signal changes will relate directly to the concentration of drug present in the bloodstream at any given time. A third method used pharmacodynamic models based upon the effects of quinelorane on locomotor behavior in awake animals (Figure 4). Two behavioral covariates were produced: the first was created using counts of mean locomotor activity after administration of quinelorane, and the second created using the same data after additionally subtracting locomotor activity in control animals given saline vehicle injections.

Effects of Different Models

As might be expected when using a highly selective D_2/D_3 receptor agonist compound, the pattern of quinelorane-induced BOLD signal changes visualized after comparing pre- and post-injection images (Figure 1) closely resembles the distribution of D_2 and D_3 receptors within the rat brain. High levels of D_2 and D_3 receptor mRNA and D_2/D_3 receptor ligand binding are present within the olfactory nuclei, olfactory tubercle, islets of Calleja, nucleus accumbens, and caudate-putamen [87,93–97], which closely correlates with the pattern of neuronal activation detected following quinelorane administration.

Pharmacokinetic Modeling

Creating a pharmacokinetic model from quinelorane blood concentrations and using it as a model of the expected change in BOLD signal (Figure 2) creates an SPM map that is remarkably similar to that produced using an “off/on” model, with the anterior olfactory nuclei, nucleus accumbens, and caudate-putamen being similarly activated when using both approaches (Figures 1 and 3). The statistical significance of the observed activations is

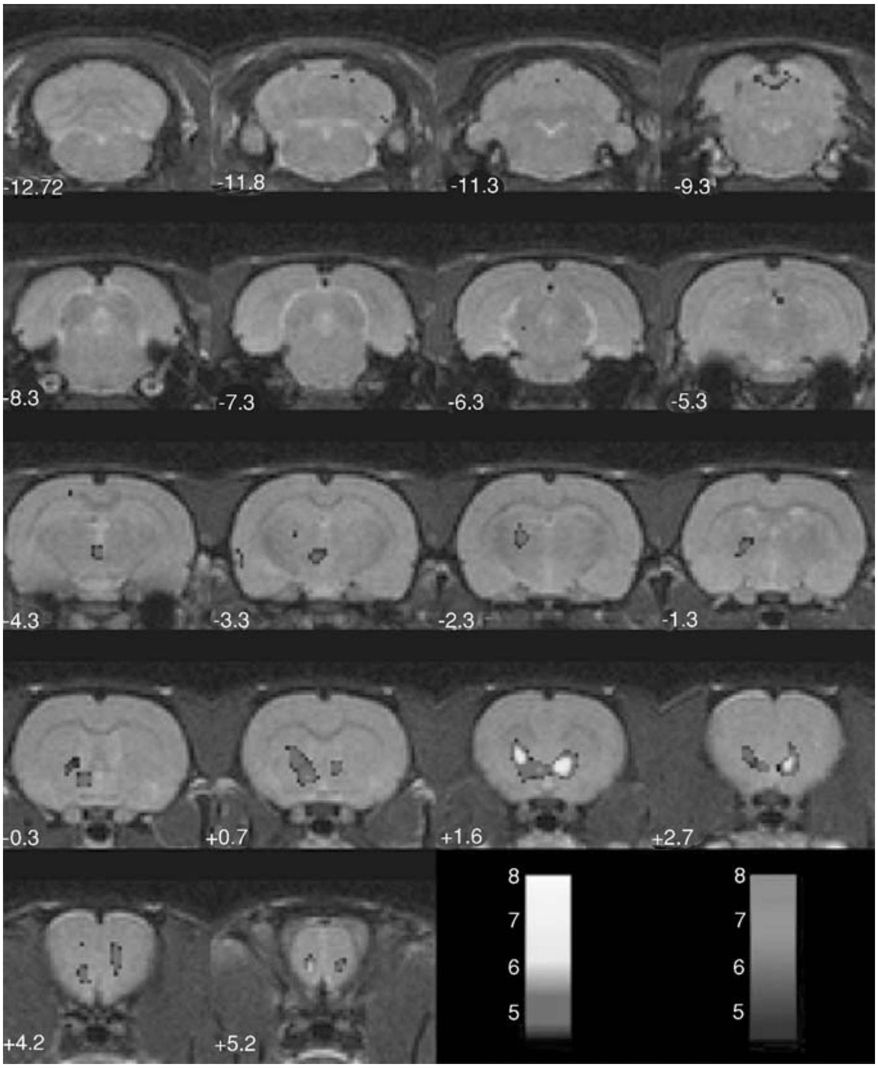

Fig. 1. Group statistical parametric map showing significant changes in BOLD contrast after administration of 30 μg/kg quinelorane ($n = 5$), testing for differences between pre- and post-injection scans. Color scales represent T scores of significant increases (red < yellow) and decreases (blue < green) in BOLD signal, where $T > 4.5$, $p < 0.05$, corrected for multiple comparisons. Activation maps are overlaid on a T_2-weighted spin echo anatomical image, with each contiguous slice being 1 mm thick and moving rostrocaudally through the brain from bottom right to top left, with approximate co-ordinates relative to Bregma [108]. (See also Plate 75 on page L in the Color Plate Section.)

also similar with both models. This suggests a significant correlation between the time course of changes in blood quinelorane concentration and the observed BOLD signal changes in activated regions and that there may be a direct link between the level of activity in these brain regions and the amount of drug present within the blood.

Behavioral Modeling

Using a model based on the biphasic locomotor effects of quinelorane that takes no account of changes in the behavior of control animals (Figure 4, blue curve), produces SPM maps that are almost entirely devoid of statistically significant changes in BOLD contrast (Figure 5). However, in contrast to the results produced using either

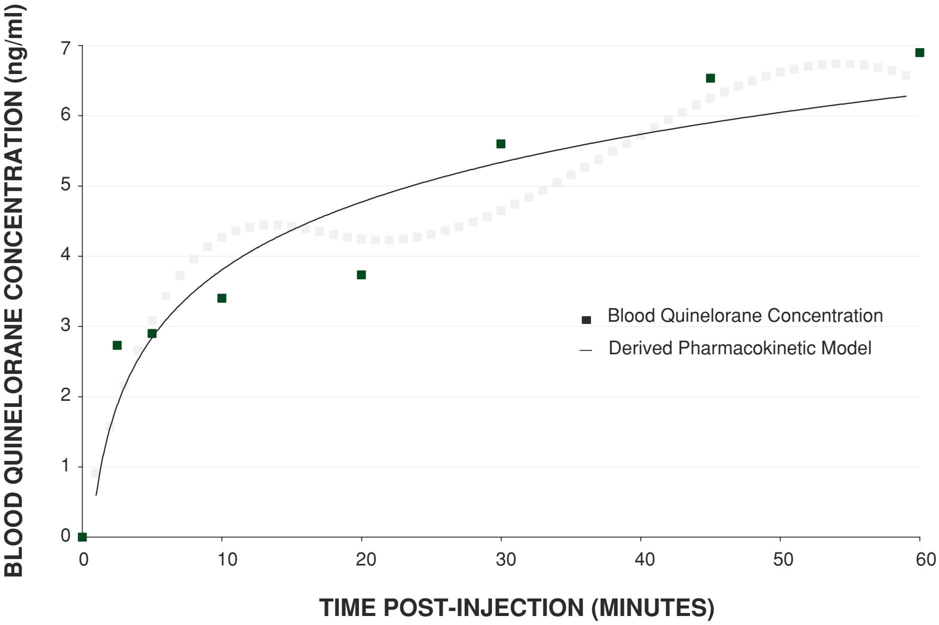

Fig. 2. Mean blood quinelorane concentration following administration of 30 μg/kg quinelorane ($n = 3$) (solid squares) and derived pharmacokinetic model after interpolation of blood quinelorane levels (solid line).

the "off/on" or pharmacokinetic models, small bilateral increases in BOLD signal were noted in the entorhinal cortex and posterior piriform cortex and small bilateral decreases in BOLD signal were present within the nucleus accumbens. The lack of statistically significant BOLD signal changes using this model is likely to be due to the biphasic shape of the curve used to model BOLD changes against. For there to be a statistically significant relationship between the model and data, BOLD signal changes would have to first decrease and then increase post-injection. The lack of statistically significant changes observed using this model shows that, with the exception of entorhinal and posterior piriform cortices, most brain regions do not show biphasic changes in BOLD contrast i.e. decreased then increased signal matching the drug-induced changes in locomotor activity at this drug dose.

Using a model derived from the locomotor effects of quinelorane after adjustment to account for changes observed in control animals (Figure 4, green curve) produces statistical parametric maps that are similar to those produced using an "off/on" model (Figure 6). Bilateral increases in BOLD contrast are observed in the anterior olfactory nuclei, nucleus accumbens, and caudate-putamen, with additional unilateral increases in BOLD signal within some cortical regions. Interestingly, BOLD signal increases within the olfactory nuclei and nucleus accumbens are more statistically significant (and those changes in the caudate-putamen less significant) when modeled against the adjusted behavioral covariate than when using an "off/on" model. The adjusted behavioral covariate therefore provides a better estimate of the temporal profile of changes in BOLD signal within these regions than does an "off/on" model. This is reflected by a highly significant Pearson correlation coefficient between the adjusted behavioral model and the observed BOLD signal change in the nucleus accumbens (Figure 7), which explains the increase in statistical significance found when using this model when compared to those changes detected using a simple "off/on" model.

These contrasting approaches to analysis of phMRI data demonstrate the importance of model selection when analyzing phMRI data. With the exception of the behavioral model that was not adjusted to account for locomotor effects in control animals, all models produced similar SPM maps of significant BOLD signal changes, with small variations in the spatial extent of activations within different brain regions and statistical significance of observed changes. The lack of marked differences in observed patterns of activation when using these different models is due to each model being very similar in terms of having a rapid increase in the measured variable following drug administration that remains elevated for the duration of the experiment. These results suggest that

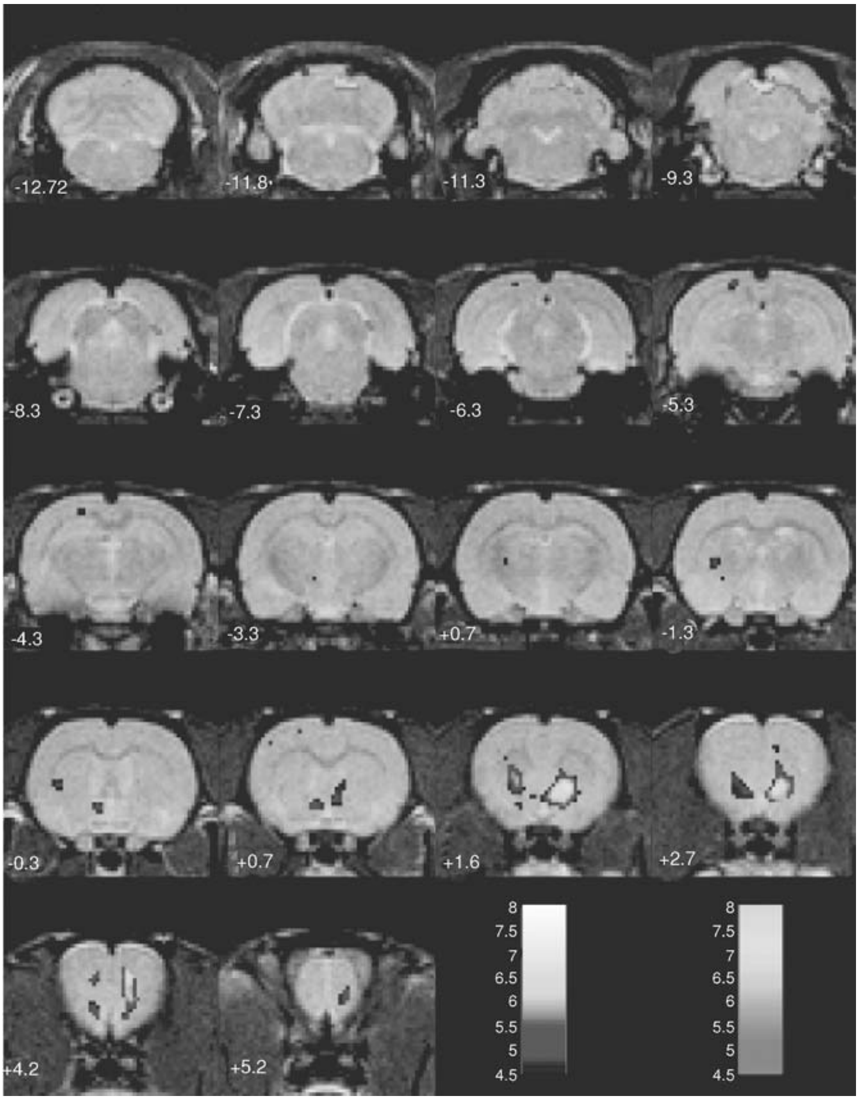

Fig. 3. Group statistical parametric map showing significant changes in BOLD contrast after administration of 30 μg/kg quinelorane ($n = 5$), analyzed using a covariate derived from quinelorane blood pharmacokinetics (Figure 2). Color scales represent T scores of significant increases (red < yellow) and decreases (blue < green) in BOLD signal, where $T > 4.5$, $p < 0.05$, corrected for multiple comparisons. Activation maps are overlaid on a T_2-weighted spin echo anatomical image, with each contiguous slice being 1 mm thick and moving rostrocaudally through the brain from bottom right to top left, with approximate co-ordinates relative to Bregma [108]. (See also Plate 76 on page LI in the Color Plate Section.)

quinelorane activates a range of limbic and basal ganglia regions in a similarly rapid and sustained fashion, with activation occurring almost immediately after drug injection and being sustained for the remainder of the experiment. Using a series of different models in this way can yield useful additional information, particularly where a drug has an effect on several behavioral measures at different times following administration, and also where pharmacokinetic and pharmacodynamic measures are temporally divergent. Many studies have used intravenous drug

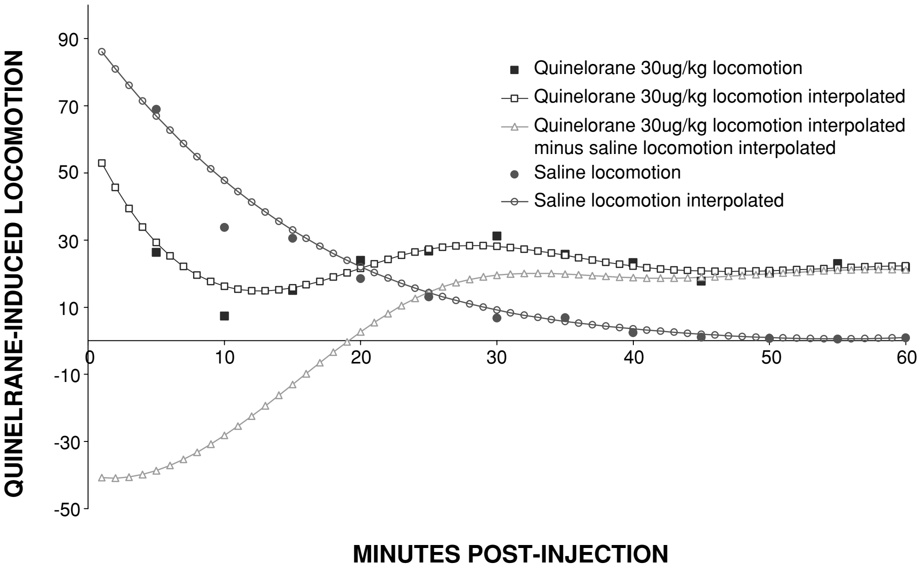

Fig. 4. Covariates derived from locomotor activity after administration of saline (red curve), 30 μg/kg quinelorane (blue curve), and after subtraction of locomotor activity in control animals from that of treated animals (green curve) in arbitrary units. (See also Plate 77 on page LII in the Color Plate Section.)

injections when producing pharmacokinetic models, with the advantage that the downward slope of the pharmacokinetic curve produced by more rapid drug clearance helps to reduce autocorrelations between the model and other confounding signal changes (such as global effects or scanner signal drift) within a time series. Whilst increasing the statistical power of analysis by allowing multiple periods of drug "stimulation," intravenous injections are liable to cause additional physiological confounds such as marked changes in systemic blood pressure that may lead to non-neurogenic BOLD signal changes. Repeated drug challenges may, over a short time period, also affect the response to drug as receptors become progressively desensitized, and giving drugs via intravenous rather than other routes can also make comparisons with the behavioral effects of a drug in awake animals more difficult. Nevertheless, it may be desirable to compare the effects of different routes of drug administration where this alters the time course of drug-induced behavioral and BOLD signal changes in order to isolate changes in those regions of the brain that mediate particular aspects of a drug's behavioral effect.

Accounting for Changes in Physiological Measures

As BOLD contrast is dependent on rCBF, factors unrelated to neuronal activity which may cause rCBF to increase must be controlled as carefully as possible. In the phMRI experiments using quinelorane described here, less than 20% of treated animals showed a small, transient increase in heart rate and blood pressure between 5 and 10 min after administration of quinelorane. This lack of cardiovascular changes, combined with observed BOLD signal changes being localized and not global in nature, make it unlikely that the changes in BOLD signal result from the systemic effects of quinelorane. It is also important to consider the possible effects that confounding changes in global signal intensity, which may result in part from the systemic effects of a drug, may have on the results of a phMRI experiment. For this study, changes in global signal intensity were tested against each of the models used in the data analysis to ensure that there was no statistically significant correlation between them. Having provided this assurance, the global signal was then included within the statistical model used for analysis (ANCOVA).

Confounding Drug Effects on Cerebral Blood Vessels

Dopamine is known to play a role in the regulation of cerebral blood flow, as dopaminergic axons innervate intraparenchymal microvessels within the cortex, and dopamine elicits dose-dependent reductions in the diameter of such vessels [98]. Such dopaminergic regulation

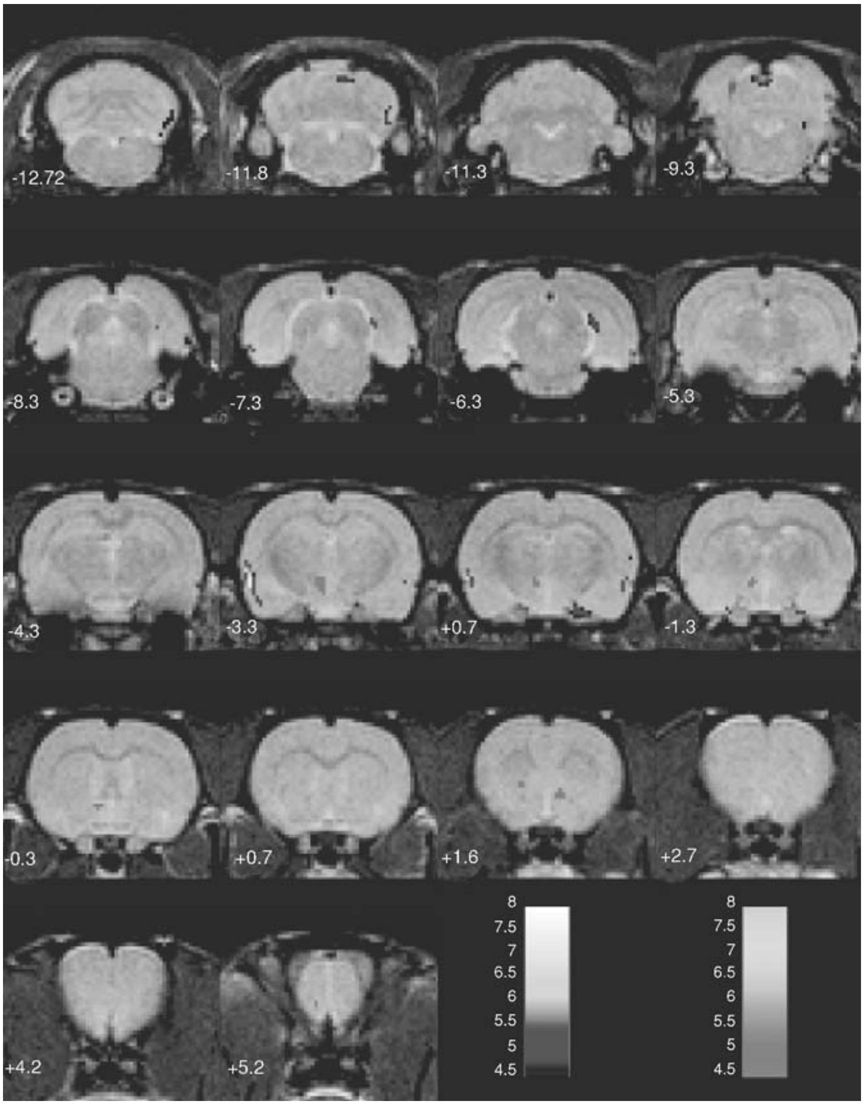

Fig. 5. Group statistical parametric map showing significant changes in BOLD contrast after administration of 30 μg/kg quinelorane ($n = 5$), analyzed using a covariate derived from the locomotor effects of 30 μg/kg quinelorane (Figure 4). Color scales represent T scores of significant increases (red < yellow) and decreases (blue < green) in BOLD signal, where $T > 4.5$, $p < 0.05$, corrected for multiple comparisons. Activation maps are overlaid on a T_2-weighted spin echo anatomical image, with each contiguous slice being 1 mm thick and moving rostrocaudally through the brain from bottom right to top left, with approximate co-ordinates relative to Bregma [108]. (See also Plate 78 on page LII in the Color Plate Section.)

of local cerebral cortical blood flow raises the possibility that quinelorane may be acting directly at receptors on cerebral blood vessels to elicit BOLD signal increases without a corresponding change in underlying neuronal activity. Both apomorphine and the D_1 receptor agonist SKF-38393 dose-dependently increase the diameter of cortical arterioles *in vivo*, an effect blocked by the D_1 receptor antagonist SCH23390, suggestive of D_1 receptor mediated effects [99]. In contrast, the D_2/D_3 receptor agonist quinpirole increases vessel diameter only at

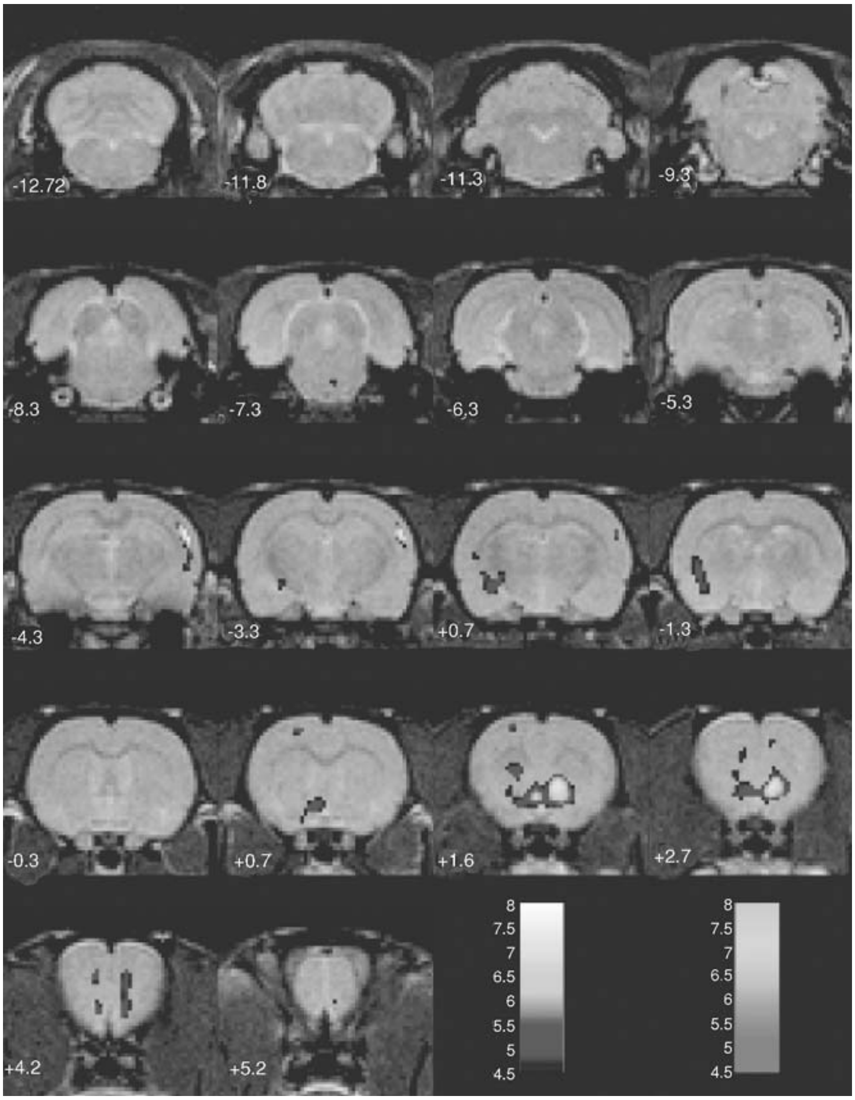

Fig. 6. Group statistical parametric map showing significant changes in BOLD contrast after administration of 30 μg/kg quinelorane ($n = 5$), analyzed using a covariate derived from the locomotor effects of 30 μg/kg quinelorane accounting for locomotor changes in control animals (Figure 4). Color scales represent T scores of significant increases (red < yellow) and decreases (blue < green) in BOLD signal, where $T > 4.5$, $p < 0.05$, corrected for multiple comparisons. Activation maps are overlaid on a T_2-weighted spin echo anatomical image, with each contiguous slice being 1 mm thick and moving rostrocaudally through the brain from bottom right to top left, with approximate co-ordinates relative to Bregma [108]. (See also Plate 79 on page LIII in the Color Plate Section.)

high agonist concentrations, possibly via effects at histamine H_2 receptors. Dopamine-mediated vessel constriction may involve activation of α-adrenoceptors and 5-HT receptors, as the effects of dopamine-induced vasoconstriction can be blocked by adrenergic and serotonergic antagonists like phentolamine and methysergide [99,100]. The effects of dopamine and dopaminergic agonists on cortical blood vessels therefore appear to be primarily mediated by D_1 receptors and/or non-dopamine receptors, and as quinelorane has extremely low affinities for

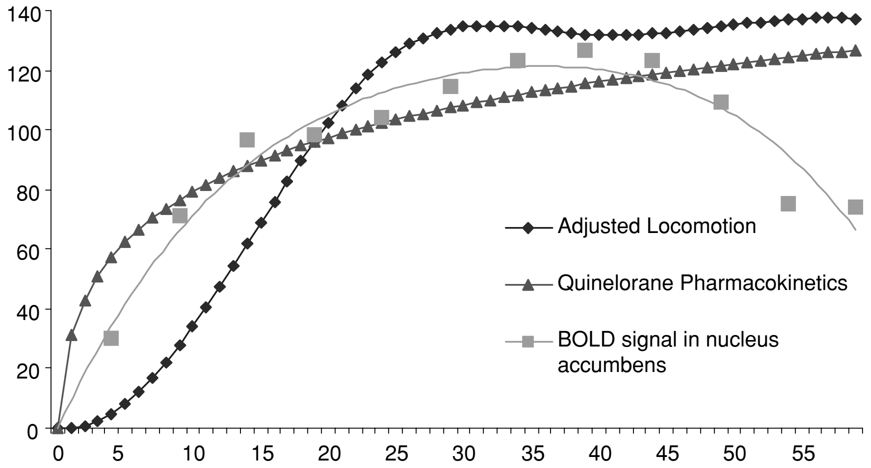

Fig. 7. Comparison of covariates used in phMRI analysis representing locomotor activity induced by 30 μg/kg quinelorane after accounting for changes in activity in control animals (blue), quinelorane blood pharmacokinetics (red), and observed BOLD signal change in the nucleus accumbens after grand mean scaling to 100 for comparative purposes. (See also Plate 80 on page LIV in the Color Plate Section.)

D_1 and non-dopamine receptors [84], it is unlikely that BOLD signal changes elicited by the low dose of quinelorane used in the experiments presented here result from a direct drug effect on cerebral blood vessels. It might also be expected that dopaminergic innervation of the cerebral vasculature might occur throughout the brain, and that any direct activation of cerebrovascular dopamine receptors would produce more global patterns of change in blood flow rather than the localized BOLD changes observed following quinelorane administration. However, the intimate relationship between the dopaminergic system and the regulation of CBF represents a potentially serious confound for all phMRI studies using dopaminergic agonists and antagonists, and particular care is needed when both planning and interpreting the results of such experiments in order to minimize these confounds.

Explaining the Absence of Signal Changes

It is also important to consider why activity in regions of the brain that might be expected to respond to a particular drug appears unchanged. For example, the lack of observed BOLD signal response to quinelorane through more widespread dopaminergic regions such as the substantia nigra and ventral tegmental area may be due to a variety of factors. Firstly, there may be no changes in neuronal signaling within these regions and so no corresponding change in BOLD signal. The lack of quinelorane-induced changes in BOLD signal within the substantia nigra may therefore reflect a lack of alteration in neuronal activity in this area. Alternatively, any changes in activity within these nuclei may not be of sufficient magnitude to elicit a detectable BOLD response. As BOLD signal is likely to reflect increased neuronal signaling at synapses rather than increased energy utilization *per se* [11], if there is no net change in the overall level of signaling between neurones, BOLD signal might remain unaffected by alterations in action potentials which have no overall effect on the signaling systems controlling blood flow. If the balance of pre- and post-synaptic activity changes without any net change in synaptic activity, then the spiking output from a particular region might alter without having any effect on the observed BOLD signal. It is also possible that if the drug under investigation has a direct effect on the cerebral vasculature, causing it to either dilate or constrict, this may directly counter any changes in rCBF that might be expected to occur as a result of modulated neuronal activity and so prevent a change in BOLD signal from being observed. When interpreting the results of phMRI experiments, it is therefore important to bear in mind that the absence of a change in BOLD signal cannot necessarily be taken as proof that no change in neuronal activity within a particular brain region has occurred.

Effects of Anesthesia

Of particular concern when interpreting phMRI results is the effects of the anesthetic agent used on resulting patterns of brain activity. The effects of α-chloralose on neurotransmission are not well understood, with contradictory reports suggesting that it depresses basal dopamine levels and dopamine release in response to sensory stimulations in the caudate-putamen and substantia nigra of the cat [64], but has little or no depressive effects on central dopaminergic metabolism and neurotransmission in the rat [101,102]. α-chloralose has also been shown to enhance GABAergic function by increasing the affinity and efficacy of GABA at GABA_A receptors [103]. For these reasons, it has been suggested that α-chloralose may not be a suitable anesthetic for phMRI investigations of the dopamine system. However, our results show that α-chloralose is suitable for detecting the effects of D_2/D_3 receptor agonist-induced changes in brain activity using BOLD phMRI. As spatial patterns of quinelorane-induced activity closely match D_2/D_3 receptor distribution patterns, α-chloralose may produce a state of low basal activity within the dopaminergic system, allowing phMRI to detect the primary site of dopamine receptor agonist action within the brain. This possibility is supported by a phMRI study showing that rCBV changes in the cortex and basal ganglia that follow the administration of either cocaine or amphetamine are preserved under halothane anesthesia, but are considerably diminished or absent under α-chloralose anesthesia [104]. This study also reported that following a challenge with the D_2-like receptor antagonist clozapine, rCBV increases are observed throughout the striatum under halothane anesthesia, but are much diminished when α-chloralose is used instead [104]. These data suggest that α-chloralose decreases basal dopamine release, diminishing the actions of drugs that act either by inhibiting dopamine reuptake (e.g. cocaine and amphetamine), or are antagonists like clozapine and produce their functional effects by blocking the actions of endogenous dopamine. As quinelorane is a direct agonist at D_2/D_3 receptors, its effects are not dependent on either modulating or blocking endogenous dopamine, and so the actions of quinelorane at dopamine receptors would be unaffected by any α-chloralose-induced modulation of dopamine release. α-chloralose anesthesia has been shown to lower the cerebral metabolic rate of glucose utilization (CMR_{gluc}) compared to the unanasthetized state, but upon activation induced by somatosensory stimulation, the final level of CMR_{gluc} increases to the same level in both states [105]. Thus a larger incremental increase in CMR_{gluc} occurs during activation in the anesthetized state (in order to reach the same final level of activity), and this larger increase in CMR_{gluc} may, in turn, produce a larger BOLD signal change. In this way, α-chloralose may actually serve to enhance the observed BOLD response to certain compounds.

Appropriate use of phMRI

In summary, there are several points that must be considered and incorporated into every phMRI experiment in order to have confidence in the final results. When considering whether a particular drug is suitable for investigation using phMRI, the known (or likely) effects that the drug may have directly on cerebral blood vessels, and hence CBF and CBV, need to be taken into account. If anesthesia is used, it must be at the lowest ethically acceptable level in order to minimize the confounding effects on drug-induced neuronal activation. Consideration should also be given to the known effects of different anesthetics on neurotransmitter systems. During the phMRI experiment, it is vital that extensive physiological monitoring is undertaken to provide confidence that any drug-induced patterns of activation are neuronal in origin. To do this, changes in heart rate, blood pressure, or respiration must be shown not to correlate with observed BOLD signal changes. In a similar fashion, changes in global signal should also be tested for correlations with the model of the expected BOLD signal response being used in the analysis. If patterns of activation truly result from drug-induced changes in neuronal activity, then it is likely that they will bear some resemblance to either the distribution of receptors to which that drug binds, or to the innervation of neurones within the neurotransmitter system affected by the drug. The less specific the compound being studied in terms of receptor binding profiles, then the more difficult it will be to provide certainty that patterns of activation genuinely reflect changes in neuronal activity. It may also be preferable to use smaller drug doses whenever possible in order to minimize any unwanted systemic effects and activate as selective a population of receptors within the brain as possible.

The Future of phMRI

The explosion in phMRI studies over recent years have shown both the potential this technique has for revealing the mechanisms by which drugs act in the brain and also the variety of different experimental situations where it can be employed. The major advantage phMRI has over other techniques is the detailed time course information it provides. PhMRI has shown how drugs with similar mechanisms of action, like cocaine and amphetamine which act on overlapping brain regions and neurotransmitter systems, can differ greatly in their onset and duration of effect. In addition, phMRI has also demonstrated a way in which the route of administration and dose can affect the measured phMRI response and thus neuronal activity. This time course information allows an assessment to be made of the brain circuitry that underlies a given drug response.

As the use of phMRI becomes more routine and techniques are increasingly refined, the key advantage that phMRI has in allowing longitudinal assessment of changes in brain functioning over time will become increasingly important. Most clinically used compounds exert their effects only after chronic treatment, and whilst this process is difficult to investigate in detail with current, highly invasive techniques, phMRI is ideally suited to investigating the change in receptor responses that follows repeated drug administration. In addition to assessing acute drug effects in naïve animals, as phMRI becomes more established it will be interesting to examine the effects of drugs in specific animal disease models, as has already begun in models of addiction and drug tolerance [40,41], cerebral ischemia [106], or assessing the effects of drug interactions, like those between dopamine agonists and antagonists [67]. There is also undoubted utility for phMRI within drug discovery in areas where the synthesis of a radioligand for either PET or autoradiography is difficult, or the allosteric action of a particular drug prevents the use of a ligand.

To date, most studies have relied either on drugs producing regionally specific modulations in BOLD or rCBV in order to negate the possibility that signal changes may be purely vascular and not neuronal in origin. In future, cross-validating the results of phMRI experiments with those produced by other measures, such as electrophysiology in humans [107], local field potentials [32], microdialysis [52], or metabolic markers will become increasingly important to substantiate the findings of phMRI studies, particularly as phMRI comes to be applied in an increasingly more sophisticated fashion involving the use of compounds with an unknown mechanism of action. Such complex experimental designs will also necessitate new data analysis techniques, particularly those that require no *a priori* knowledge of the time course over which a drug acts, and methods of studying drug-induced modulation in functional connectivity between different brain regions.

Application of MRI to Cell Tracking

Kishore Bhakoo, Catherine Chapon, Johanna Jackson, and William Jones
Stem Cell Imaging Group, MRC Clinical Sciences Centre, Imperial College London, London W12 0NN, UK

Introduction

Cell replacement therapy is undergoing a critical transition from being a discipline of the basic sciences to being recognized as a potential component of medical practice. For multiple tissues, the use of stem cell transplantation to replace cells lost due to traumatic injury or chronic degenerative processes is being pursued in a wide range of experimental models. Cell-based therapies [1] have received much attention as novel therapeutics for treatment of cancer [2], autoimmune [3], cardiovascular [4], inflammatory [5], and degenerative diseases [6,7]. A number of native cells, antigen-specific T-lymphocytes [8], or, more recently, stem and progenitor cells have been used for these approaches. Such treatment offers the possibility of treating a wide range of serious degenerative diseases that affect millions of people worldwide for which there are currently no cures.

The recognition that cell transplantation can be used for tissue repair is associated with recognition of the considerable challenges involved in implementing this approach in the clinical arena, with one of the most significant challenges being the non-invasive analysis of transplanted cells and their progeny. While multiple approaches can be used to analyze survival, dispersion, and differentiation of transplanted cells in experimental animals, none of them can be applied to clinical analysis. Whether one considers *ex vivo* cell labeling with fluorescent dyes or transplantation of cells expressing reporter genes (e.g. β-galactosidase, green fluorescent protein), these are methods that involve sacrifice of the animal and removal of tissue for histological procedures [9,10]. Thus, these approaches cannot be translated to human studies.

Development of methods for monitoring cell grafts non-invasively, with sufficiently high sensitivity and specificity to identify and map the fate of transplanted cells, is an important aspect of application and safety assessment of stem cell therapy. MRI methods are potentially well suited for such applications as this produces non-invasive “images” of opaque tissues or structures inside the body and more importantly can be translated for pre-clinical assessments.

Due to the seamless integration into the host parenchyma, and migration over long distances, cell grafts cannot be detected based on their mass morphology. To monitor cell migration and positional fate after transplantation, current methods use either reporter genes or chimeric animals. These methods are cumbersome, involve sacrifice of the animal and removal of tissue for histological procedures, and cannot be translated to human studies [9,10]. Therefore, development of methods for monitoring cell grafts non-invasively, with sufficiently high sensitivity and specificity to identify and map the fate of transplanted cells, is an important aspect of application and safety assessment of stem cell therapy. MRI methods are potentially well suited for such applications as this produces non-invasive “images” of opaque tissues or structures inside the body.

For transplanted cells to be visualized and tracked by MRI, they need to be tagged so that they are “MR visible”. At present there are two types of MRI contrast agents used clinically. These are gadolinium chelates (e.g. Gd^{3+}-DTPA) or iron oxide nanoparticles. However, these reagents were designed as blood-pool contrast agents and are impermeable to cells. Several approaches have been deployed to enhance cell labeling to allow *in vivo* cell tracking by conjugating MRI contrast agents to a range of ancillary molecules to enhance their uptake. With the growing array of cell labeling techniques, cells tagged with various monocrystalline MR probes have been evaluated both *in vitro* and *in vivo* [11–13].

Methods for monitoring implanted stem cells non-invasively *in vivo* will greatly facilitate the clinical realization and optimization of the opportunities for stem cell-based therapies. Other than tracking stem cells, there are numerous examples where similar methodologies of cell tracking can aid in clinical diagnosis, such as those from a tumor or following an inflammatory response.

Intracellular MRI Contrast Agents

Recent work in the design of MRI contrast agents has opened up the possibility of combining the spatial resolution available of MRI for anatomic imaging with the ability to “tag” cells, and thus enable non-invasive detection and study of cell migration from the site of implantation. *In vivo* monitoring of stem cells after grafting is essential for understanding their migrational dynamics, which is an important aspect in determining the overall therapeutic

index of cell therapies. Despite recent advances in both the synthesis of paramagnetic molecules and the basic cell biology, methods for achieving effective cell labeling using molecular MR tags are still in their infancy.

Properties of a Good Contrast Agent for Cell Tracking

Before discussing the design and utilization of contrast agent to label cells for *in vivo* tracking by MRI, there are several parameters that need to be considered when synthesizing an efficient contrast agent. Firstly, there is a need to deliver sufficient amounts of MRI contrast agent into cells and achieve intracellular retention. Once the contrast agent is loaded into the cells, there is a need for efficient relaxivity to obtain a high *in vivo* MR signal-to-noise ratio. An additional aspect for successful design is tolerable cytotoxicity of the MRI contrast agent, which should have no long-term effects on cell viability, nor compromise cellular function, e.g. metabolism and differentiation.

MRI Contrast Agent for Cell Tracking

MRI contrast agents can be classified as either paramagnetic or superparamagnetic and will be discussed in some detail below.

Paramagnetic Agents

Where an element has one or more unpaired electrons, it is said to be paramagnetic, as it possesses a permanent magnetic moment. Examples of these are Fe^{3+}, Mn^{2+}, and Gd^{3+}. The more unpaired electrons present, the greater the magnetic moment. The effect of the magnetic moment in solution results in a dipolar magnetic interaction between the paramagnetic ion and neighboring water molecules. A fluctuation in this magnetic interaction produces a decrease in $T1/T2$ relaxation time [14]. Paramagnetic compounds produce, predominantly, a $T1$ effect, giving a hyperintense region. In order to avoid the problems associated with toxicity *in vivo*, heavy metal ions are chelated with organic moieties in order to make them more biocompatible (Figure 1a).

An in-depth discussion of the mechanism underlying the enhancement of relaxation is examined by Merbach and Toth [14].

Superparamagnetic Agents

The other class of contrast agents is superparamagnetic compounds. These consist of an iron oxide core, typically 4–10 nm in diameter, where several thousand iron atoms are present. A biocompatible polymer surrounds the core to provide steric and/or electrostatic stabilization. This is required due to the large surface area to volume of the nanoparticles. If no stabilization is present, the particles spontaneously precipitate out of solution due to colloidal instability. The polymers used to stabilize the iron oxide core are typically polysaccharide-based (e.g. dextran and starch) but others have also been used, e.g. polyethylene glycol (PEG).

There are two types of superparamagnetic contrast agents, superparamagnetic iron oxide (SPIO) and ultra small superparamagnetic iron oxide (USPIO). The difference between the two is illustrated in Figure 1b and c, where SPIOs consist of several magnetic cores surrounded by a polymer matrix and USPIOs are individual cores surrounded by a polymer. Superparamagnetic contrast agents provide predominantly a $T2$ effect, but smaller particles have shown to act as a $T1$ agent [14]. The relaxation mechanism for superparamagnetic particles is discussed more extensively in a review by Roch *et al.* [15].

SPIOs are clinically contrast agents approved by the Food and Drug Administration (FDA) for hepatic reticuloendothelial cell imaging, and are in Phase III clinical trials as blood-pool agents for use in lymphography [16]. Iron oxide particles are also being developed for a variety of different applications, namely: (a) as magnetic navigation devices for the targeted delivery of therapeutics [17,18]; (b) hyperthermia-induced tumor therapeutics under high-frequency magnetic fields [19]; and (c) for magnetic cell sorting [20]. More importantly, SPIO particles are biodegradable and can be degraded and assimilated within the body.

More recently, a new class of modified USPIO has been produced known as cross-linked iron oxide (CLIO), whereby the dextran coat of the USPIO is cross-linked in the presence of epichlorohydrin, and then aminated to produce amine-terminated nanoparticles suitable for conjugation [21].

Therefore, the concept of labeling cells with one of these classes of contrast agents is extremely attractive, as one could then visualize transplanted cells non-invasively by MRI; where the labeled cells would produce either hyperintense or hypointense depending on the class of contrast agent chosen. However, most efforts to engineer cell tagging agents has concentrated on using superparamagnetic nanoparticles as they possess higher sensitivity, especially on the higher field research scanners that are now being implemented for pre-clinical or clinical studies.

Engineering Delivery Systems for Iron Oxide Contrast Agents

However, none of the iron oxide-based contrast agents available for clinic studies were designed to go across cellular membranes. Therefore, numerous efforts have been made to deliver iron oxide particles into a variety of cells. One such molecule that is emerging as a useful reagent relies on the covalent binding of CLIO particles to the HIV-1 TAT peptide to enhance cellular uptake [11,13,22–24].

TAT peptide contains a membrane-translocating signal that efficiently shuttles the particles into cells and the nuclear compartment [25]. A similar approach involves the covalent conjugation of internalizing monoclonal antibodies onto SPIO particles leading to cellular uptake via endosome-mediated mechanisms [26]. Alternatively, conjugations of SPIOs with antibodies to cell surface antigens have also been deployed with some success [27]. Nevertheless, these methods are inherently restrictive to the particular antibody–receptor interaction on the target cell line. Other methods involve the use of transfection reagents, such as those developed for the translocation of plasmid DNA into cells [28]. Even though this approach offers a more universal way to transfer iron oxide particles intracellularly, it suffers from the variability in cellular labeling; but more importantly some of these reagents have cytotoxicity characteristics associated with highly cationic transfection agents (TAs). A more detailed summary of these methods is outlined below.

Delivery of Contrast Agent with Transfection Agents

TAs have been developed commercially for the delivery of genetic cargo into cells for gene therapy applications. Such delivery systems are based on different platforms, such as liposomes, cationic dextrans, dendrimers, etc. These delivery systems are usually cationic to allow a favorable interaction between both DNA–TA and TA–cell surface (both DNA and cellular surface are anionic). The mechanism affording interactions between DNA and TA are predominantly electrostatic, although van der Waals forces will also be present.

The use of TAs with clinically approved contrast agents has resulted in successful labeling of several cell lines [28–32]. Complexation between the contrast agent and the TA depends on the nature of the contrast agent itself. However, where a low surface charge is present on the contrast agent, van der Waals forces will predominate. The contrast agent–transfection agent complex enters the cell by endocytosis, shown in Figure 2.

The principle advantage of using this technology is its wide availability. Commercially developed transfection kits (lipofectene, SAINT-Mix, poly-L-lysine, etc.) can be obtained from several manufacturers and have been used in conjunction with easily available contrast agents (Sinerem®, Endorem®, etc.).

The disadvantage of such a system is that the protocol must be optimized for every cell type [33], and the TAs themselves usually pose various levels of toxicity [34]; again these are cell-type dependent. It is therefore necessary to optimize the contrast agent/transfection agent ratio, in order to maintain a fine balance between labeling efficiency and cellular toxicity. Another drawback of this system is that the interaction between the contrast agent and the TA can result in a decrease in $T1$ and $T2$ relaxivity [29]. Furthermore, studies have also demonstrated that the more effective TAs have greater cytotoxic effects [34].

Delivery of Contrast Agent Using Specific Targeting

A distinct advantage of developing *de novo* contrast agents is the opportunity to incorporate specific molecular

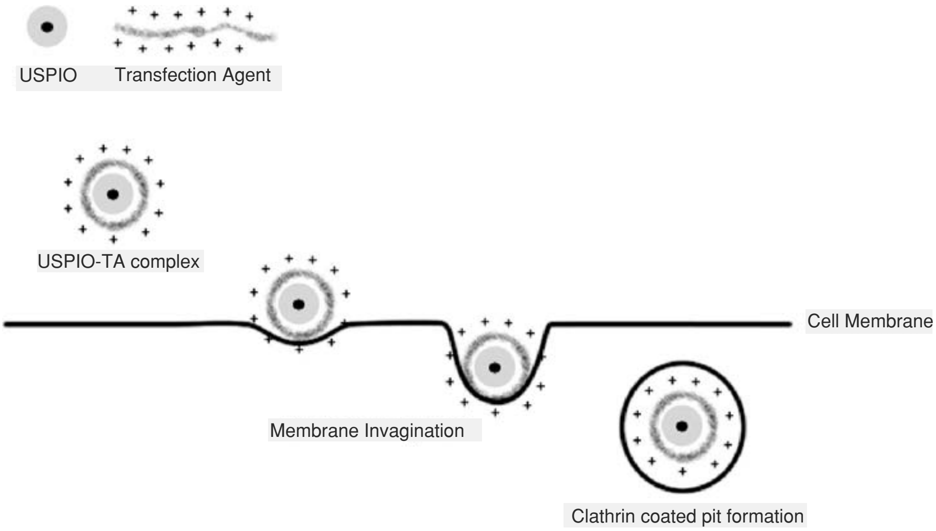

Fig. 2. Schematic of the complexation of USPIO with a transfection agent and subsequent cellular uptake via endocytosis.

targeting to increase the efficiency of cellular labeling. Many different methods have been used to deliver contrast agents and will be discussed in some detail.

Membrane Permeating Peptides

Membrane permeating peptides have received considerable attention as they can delivery cargoes of different sizes including: nanoparticles [35], liposomes [36], and fluorescein with extremely high efficiency and minimal cytotoxicity [37]. Various membrane permeating peptides sequences (peptide transduction domain, PTD) are found to occur naturally including *HIV-1* TAT, *Antennapedia* transcription factor, *Herpes simplex* virus, and VP22 transcription factor. However, the most extensively employed delivery system has been the conjugation of TAT peptide with USPIO to facilitate labeling of a range of cell types [11,35,38,39].

The precise mechanism for cellular entry has yet to be elucidated; however, there are several indications for particular structural requirements that allow for effective and efficient cellular uptake. One of the principal requirements is the presence of multiple arginine residues on the PTD for efficient cell entry. Many naturally occurring membrane-permeating peptides contain a large number of arginine residues [40]. Another requirement appears to be the presence of negatively charged glycosaminoglycans on the cell surface [41], whilst another report suggests that heparin sulfate is required on the cell surface [42]. It was originally thought that the uptake mechanism was energy independent, and thus would not involve endocytosis. Other studies suggested that the non-endosomal uptake was an artifact of the technique used to study the mechanism of cell entry [43].

Neverthless, what is clear, regardless of the exact mechanism, is that TAT and other polyarginine peptide sequences allow the shuttling of cargo across the cell membrane with high efficiency. The majority of studies that have investigated the delivery of CLIO into a variety of cells using PTDs have used the TAT peptide or a variation on the theme [13,23,39,44]. Studies have also demonstrated successful cellular labeling with gadolinium chelates conjugated with poly(arginine) with minimal of cytotoxic effects. However, there is some evidence of gadolinium chelate leakage from these cells [45,46].

Use of Antibodies

Conjugation of contrast agents to PTDs provides a 'generic' model for labeling a wide variety of cell types. However, this system lacks cellular specificity. In contrast, contrast agents conjugated to antibodies, against specific cell surface antigens, provides cellular targeting with high specificity [47]. However, targeting cell surface markers, whilst being specific, has two major drawbacks. Firstly, the presence of the nanoparticles on the surface of the cell may affect its capacity to migrate and "home" effectively. Secondly, the antibody–contrast agent complex's interaction with the cell surface antigen is reversible; thus there is a high probability that the complex can be taken up by other cells (e.g. macrophages) and provide ambiguous information on the migrational characteristics of the targeted cells. These two issues have been overcome by using the OX-26 antibody in the labeling of neural precursor cells [48], which is an internalizing antibody directed against the transferrin receptor. In this instance, uptake of the particles is through receptor-mediated endocytosis.

Other Methods for Delivering Contrast Agents

Alternative means of cell labeling with iron oxide nanoparticles have also been investigated. Recently, Gupta and Curtis have used lactoferrin and ceruloplasmin coated particles to label cells to target their respective receptors. This resulted in a decrease in toxicity where lactoferrin produced the least cytotoxic effects when compared with naked iron oxide particles [49]. However, these particles were shown not to be internalized and therefore face the same problem outlined above, namely loss of cell homing abilities or detachment of iron oxide from the cell surface.

Cytotoxicity and Metabolism

There are several important characteristics that need to be considered when designing a new contrast agent. These include its toxicity and eventual *in vivo* metabolism. It is essential that the presence of the contrast agents does not affect proliferation, differentiation, its ability to integrate into host tissues, nor its cellular function. Whilst iron oxide dextran nanoparticles have been used extensively in the clinic, these nanoparticles have remained outside the cell. Recent reports have demonstrated that the intracellular presence of dextran coated iron oxide nanoparticles induces apoptosis and affects cytoskeletal properties [50]. However, in this instance only the core of the iron oxide was investigated and was quoted to be 7.8 nm by magnetic measurements. It is likely that the overall hydrodynamic radius would play an important role in the disruption of intracellular structures. Thus, particles with a smaller hydrodynamic radius may pose fewer cytotoxic effects.

The mechanism of iron oxide metabolism *in vivo* has been known for a number of years, as these iron oxide nanoparticles were original produced for the treatment of severe anemia. It was found that the primary mechanism was the assimilation of exogenous iron oxide into the iron cycle [51] and is incorporated into rapidly regenerating hemoglobin [52].

Conjugation Chemistry: Attaching Contrast Agent to Delivery Ligand

As discussed previously, there are several methods for enhancing the uptake of contrast agents. In this section, we will discuss the means of conjugating PTDs and antibodies to contrast agents. In the case of USPIOs, there are two ways in which conjugation can be accomplished: (i) direct attachment to the stabilizing polymer, in this case dextran will be used as a model system, and (ii) the conjugation via a heterofunctional linker.

Conjugating Directly to USPIO: Oxidation-Reductive Amination

Whilst USPIOs are coated with hydroxyl groups present on dextran backbone, these groups are relatively unreactive in an aqueous environment. To allow direct conjugation, it is therefore necessary to introduce aldehyde moieties through selective oxidation of vicinal glycols in the presence of sodium periodate as shown in Figure 3.

It is then possible to produce an imine by reacting the aldehyde in the presence of an amine-terminating moiety. The imine however is unstable and therefore selective reduction of the imine is achieved through the use of sodium cyanoborohydride (Figure 4).

Whilst this approach has been used successfully for conjugating biological moieties [53,54], this conjugation method can give rise to several problems. Firstly, there may be reduced affinity of the conjugated ligand, probably due to steric hindrance from the dextran backbone [54]. Another problem that is frequently encountered is the uncontrolled oxidation of the dextran coating, resulting in particle destabilization, probably due to the degradation of the dextran [53]. Moreover, degradation was also found to occur on periodate oxidized sephadex G-25, where the dextran beads were degraded during extended exposure with sodium periodate [55]. Further problems can arise due to inconsistent reaction conditions, as it has been reported that the production of aldehydes depend on the pH of the reaction environment [56].

Introducing a Linker

An alternative method of conjugating the delivery/ targeting ligand to the contrast agent is via a linker. Nevertheless, there is still the issue of lack of reactivity of the hydroxyl groups under neutral aqueous conditions. This problem is overcome by the use of CLIO particles, where the dextran is cross-linked and then incubated in the presence of ammonia to produce amine-terminated particles. These on the other hand are relatively more reactive. It is then possible to couple the nanoparticles to a plethora of heterofunctional linkers, usually by the use of a succinimide ester activated compound as illustrated below (Figure 5).

The advantage of using this approach is the commercial availability of several succinimide esters available for

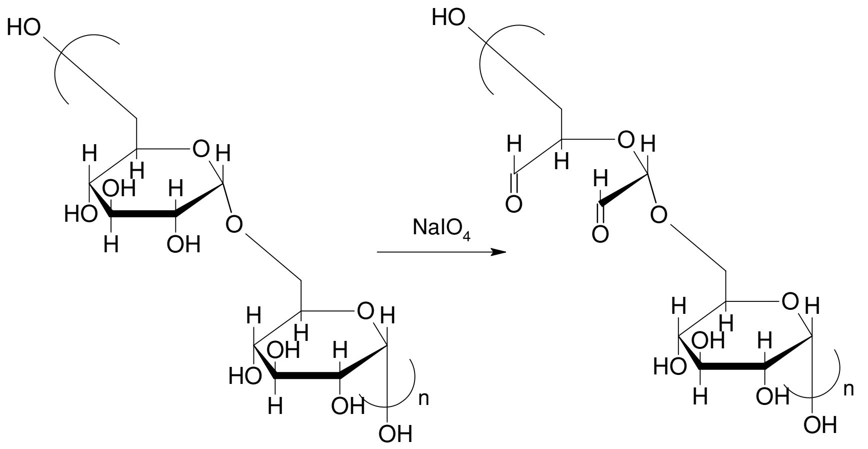

Fig. 3. Selective oxidation of neighboring hydroxyl groups in the presence of sodium periodate producing dextran polyaldehyde.

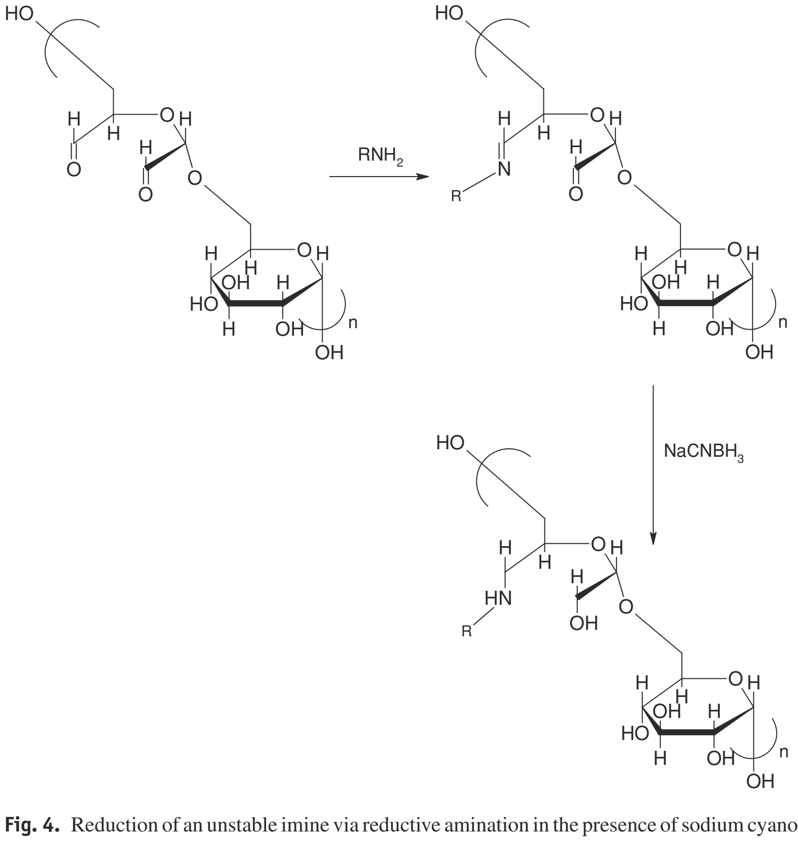

Fig. 4. Reduction of an unstable imine via reductive amination in the presence of sodium cyanoborohydride to produce a stable amine.

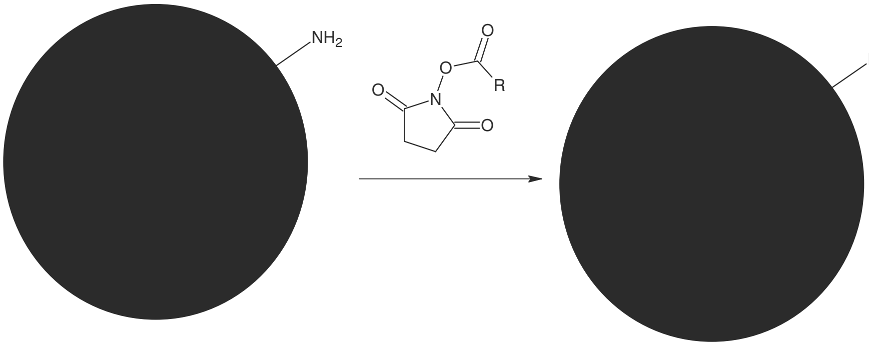

Fig. 5. Functionalization of amine-terminated nanoparticles in the presence of a succinimide ester to produce an amide, e.g. SIA, where R = CH_2I.

facile conjugation, although some can be readily prepared prior to use [57]. The disadvantage to this technique is that the *N*-hydroxysuccinimide ester is hydrolyzed under aqueous conditions.

The most common heterofunctional linkers used to date are those that allow the formation of either a thioether bond (SIA; Figure 6) or a disulfide bond (SPDP; Figure 7). These are ideal for selective conjugation to a cysteine residue either naturally present on the ligand, or introduced during synthesis. Sulfur is conjugated in preference as the rate of reaction is sulfhydryl > imidazolyl > thioether > amine [58].

SIA is preferential where a stable thioether bond is required, as SPDP produces a labile disulfide bond. The advantage of using SPDP is that the degree of conjugation can be observed by monitoring the increase in adsorption at 343 nm.

MRI Tracking of Stem Cells in the Heart

Myocardial infarction is by nature an irreversible injury. The extent of the infarction depends on the duration and severity of the perfusion defect [59]. Beyond contraction and fibrosis of myocardial scar, progressive ventricular remodeling of non-ischemic myocardium can further reduce cardiac function in the weeks to months after initial event [60].

Many of the therapies available to clinicians today can significantly improve the prognosis of patients following

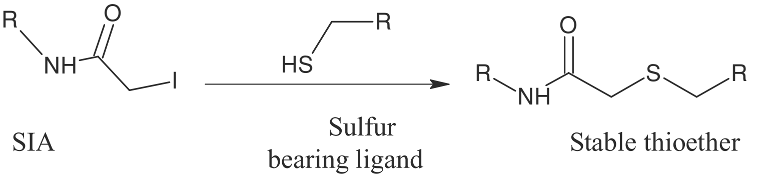

Fig. 6. Nanoparticles functionalized with SIA (where R = nanoparticle) react with sulfur bearing moieties to produce a stable thioether bond.

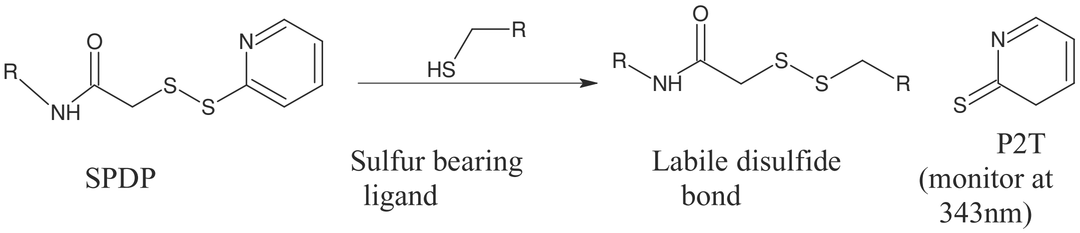

Fig. 7. SPDP derived nanoparticles (where R = nanoparticles) react with a sulfur bearing ligand to produce a cleavable disulfide bond.

an acute myocardial infarction [60,61]. However, no pharmacological or interventional procedure used clinically has shown efficacy in replacing myocardial scar with functioning contractile tissue. Cellular agents such as fetal cardiomyocytes [62], mesenchymal stem cells (MSCs) [63], endothelial progenitor cells [64], and skeletal myoblasts [65], or embryonic stem (ES) cells [66] have already shown some efficacy to engraft in the infarct, differentiating toward a cardiomyocyte phenotype, by expressing cardiac specific proteins, preserving left ventricular function and inhibiting myocardial fibrosis. Besides, *in vitro* exposure of stem cells, specifically MSCs, to specific signal molecules prior to transplantation into infarcted myocardium allows their differentiation into cardiomyocyte [67] and may facilitate a successful engraftment [68].

However, verification of the status of transplanted stem cells in animal models has been performed with histological analysis. Clinical data on stem cells transplantation is in its infancy and is very limited. But preliminary clinical data have shown that stem cell transplantation for the treatment of ischemic heart failure is feasible and promising [69]. Besides MRI was used in some clinical studies to assess the improvement of contractile function after cell transplantation [70] but without any possibility to visualize the transplanted stem cells. Therefore, the ability to label stem cells with MRI-visible contrast agents [71] should enable serial tracking and quantification of transplanted stem cells, non-invasively by MRI with high spatial resolution. The programmable nature of the imaging planes allows reproducible and volumetric coverage of the heart. Moreover, this technology scales well with subject size ranging from mouse to human.

Visualization of magnetically labeled endothelial progenitor cells transplanted intra-myocardially for therapeutic neovascularization in infarcted rats has been demonstrated with *ex vivo* MRI at 8.5 T on $T2$-weighted images [72].

Garot *et al.* [73] have demonstrated the feasibility of *in vivo* MRI tracking of skeletal muscle-derived myogenic precursor cells (MPC) pre-loaded with iron oxide nanoparticles (Endorem) injected into healthy and infarcted porcine myocardium. Iron-loaded cells in the infarcted region were detected by $T2$-weighted spin-echo MRI at 1.5 T. In addition, MRI guided the catheter for the injection of the labeled cells into the ischemic myocardium using Gd-DTPA delayed enhancement of the site. Moreover, post-mortem analysis demonstrated the presence of iron-loaded MPC at the center and periphery of the infarcted tissue as predicted by MRI.

MSCs derived from bone marrow can be detected and tracked by MRI for up to 3 weeks [74–76]. Allogeneic ferumoxides [74] or iron fluorescent particle [75,76] were given by intra-myocardial injection in a pig model of myocardial infarction. A minimum quantity of MSCs per injection was required to be MR-detectable on $T2^*$- [75] or $T2$-weighted images [74] as hypointense lesions. Indeed, Kraitchman *et al*. have shown that using a limited number of MSC injections per animal, only some (∼70%) of the injections performed in each animal can be visualized.

These promising experiments demonstrate the need for future studies to delineate the fate of injected stem cells by incorporating non-invasive tagging methods to monitor myocardial function following cell engraftment in the myocardial infarction. Consequently, MRI may lead to a better understanding of the myocardial pathophysiology as well as assessing the proper implantation and the effects of stem cell therapy by allowing a multimodal approach to evaluating anatomy, function, perfusion, and regional contractile parameters in a single non-invasive examination.

MRI Tracking of Stem Cells in the CNS

Neurodegenerative diseases where cell loss is the predominate feature of the pathology and, for which there are currently no cures, cellular replacement therapy using stem cells may provide a beneficial alternative. The efficacy of cell replacement therapy was first demonstrated using engraftment of human mesencephalic tissue into the brain of patient with Parkinson's disease [77]. Functional recovery and L-DOPA withdrawal followed by an increase in released dopamine demonstrated the functional integration of the grafted tissue. Although this was not a true stem cell transplant, it nevertheless indicated that the adult brain provides local environmental cues to undifferentiated cells to produce neuronal cell types capable of providing functional recovery.

Since this pioneering experiment, many different populations of stem cells have shown to differentiate into neural phenotypes. The most obvious choice of stem cell population would be those already derived from the neural phenotype. These include neural stem cells, found in the adult subventricular zone (SVZ) and glial-restricted precursors, found in the embryonic spinal cord. Neural stem cells have been shown to differentiate into dopaminergic neurons [78], astrocytes, and oligodendrocytes [79], and spinal cord motor neurons [80]. Surprisingly, these cells are also able to transdifferentiate into other non-neural cell types such as skeletal muscle [81]. Glial-restricted progenitors, on the other hand, are restricted to the glial lineage and produce oligodendrocytes and type-1 and type-2 astrocytes [82].

ES cells are the most pluripotent of all the stem cell populations, giving rise to many cell types in the body; thus have the greatest regenerative capacity. ES cells differentiate into a variety of neural phenotypes, including dopaminergic neurons [83], serotoninergic neurons [84], neuronal precursors [85], oligodendrocytes [86], and astrocytes [87]. There are several problems, aside from the issues of ethics, that makes ES cell therapy difficult, including the risk of inappropriate cellular differentiation and tumor formation.

Mesenchymal cells derived from bone marrow have also been shown to differentiate into neural phenotypes [88]. Additionally, rat MSCs differentiate into a mixture of neural phenotypes including astrocytes, oligodendrocytes, and neurons. Upon further differentiation, GABAergic, dopaminergic, and serotoninergic neurons may also develop [89].

Neural progenitor cells have innate migratory properties. For example, neural progenitor cells isolated from the SVZ of adult or neonatal rats, when implanted into the different regions of the neonatal brain, migrate and differentiate within regions such as the *olfactory bulb*, cortex, and *striatum*. In contrast, when grafted into the adult brain, the SVZ cells only migrated to the olfactory bulb, but not to the cortex or *striatum* [90].

MRI was used to longitudinally track the migration of SVZ cells after implantation into the healthy rat striatum using pre-labeling cells with BrdU and lipophilic dye-coated ferromagnetic particles [91]. Furthermore, MRI revealed that the area grafted with live cells appeared to expand, whereas the area implanted with dead cells, decreased in size. Immunohistochemical analysis showed that the SVZ cells differentiated into neurons (MAP-2^+ NeuN$^+$) and migrated within the striatum after being cultured with bFGF. These studies revealed only localized migration. Migration over greater distances was demonstrated using non-invasive MRI studies in a stroke lesioned animal model. It was hypothesized and later confirmed that stroke damage functions as a "chemoattractant" for neural stem cells [92]. Neural stem cells derived from the Maudsley Hippocampal Clone 36 (MHP36) cell line, were labeled with the bimodal contrast agent, GRID. This enables detection both by MRI and fluorescent histology. Following a middle cerebral artery occlusion (a rodent model of stroke), the neural stem cells were grafted unilaterally into the hemisphere contralateral to the lesion. Using a combination of GRID labeled cells and MRI, it was demonstrated that following 14 days post-transplantation; most of the cells had migrated to the ipsilateral hemisphere along the *corpus callosum* and populated the surrounding lesion area. Moreover, upon fluorescent immunochemistry, these cells were found to be GFAP$^+$ astrocytes and NeuN$^+$ neuronal precursors.

Hoehn *et al.* [93] used a similar stroke model to demonstrate the migratory properties of implanted ES cells into the brain by MRI. The cells were pre-labeled with USPIO and encapsulated with a lipofection reagent to enhance cellular uptake. The ES cells also expressed GFP as a reporter gene for immunohistochemical procedures. The labeled cells were implanted into two regions of the unaffected hemisphere: the border between the cortex and the *corpus callosum*, and the striatum. The labeled cells migrated toward the lesion in the opposite hemisphere. Strong hypointense "columns" were seen by MRI in the *corpus callosum*. These were later confirmed as migrating blankets of cells traveling toward the ischemic lesion. GFP-expressing cells were also seen in the ischemic penumbra, and in contrast to the study by Modo *et al.* [92], the majority were NeuN$^+$ suggesting that the cells had differentiated into neurons. Astrocytes and oligodendrocytes were also seen populating the surrounding area.

MRI studies have also been used to track glial progenitors labeled with contrast agent. However, in these studies MRI was used to scan post-mortem tissues, following cellular transplantation. Oligodendrocyte progenitor cells (OPCs) from the CG4 cell line have greater migratory and myelinating capacity than mature oligodendrocytes. The cells were labeled with monocrystalline iron oxide nanoparticles targeted to the transferrin receptor to aid internalization of the particles [94]. The progenitor cells were grafted into the spinal cord of a myelin-deficient rat. Cellular migration was also visualized by MRI, especially in the dorsal column. Moreover, iron oxide labeled cells, fixed with paraformaldehyde and implanted in the same way, did not migrate at all; MRI contrast was seen only at the site of injection. This also suggests that the iron oxide remains localized and is not taken up by other host cells. This is of great importance if iron oxide labeling and tracking of cells is to be used clinically. The MR images were verified by histological analysis and the lesion was found to include astrocytes, microglia, and myelin. Importantly, the Prussian blue staining correlated with that for myelin, whereas it did not overlap with the GFAP$^+$ astrocytes or microglia present. Obviously reactive gliosis and an immune reaction had occurred, but the inflammatory cells had not taken up iron oxide; the labeled OPCs were able to infiltrate the inflamed area and produce myelin.

Jendelova *et al.* [95] used MRI to study the differential response of MSCs and ES cells in rodent models of stroke (photochemical lesion) and spinal cord compression (balloon inflation). Prior to implantation, both MSCs and ES cells were labeled with Endorem and additionally co-labeled with either BrdU or GFP, respectively.

Following the induction of the lesions, either ES cells or MSCs were grafted contralateraly to the ischemic lesion. In another set of animals, either ES cells or MSCs were administered intravenously into rats with an ischemic lesion. The animals with spinal cord compression lesion were infused intravenously with MSCs. ES cells given to rats with ischemic lesions, regardless of whether given intravenously or intracerebral implantation, migrated to the lesion site within 2 weeks, as observed by MRI and subsequently confirmed with GFP visualisation. Additionally, at the site of implantation, hyper-proliferation was seen in 10% of the animals. This suggests that tumor formation had taken place, and was detected using MRI as a very large hypointense area, much larger than the other cellular transplants [95].

Implanted MSCs also migrated to the lesion area but gathered in the necrotic tissue surrounding the lesion. Few cells entered the actual lesion and of those very few differentiated into neurons, as seen 4 weeks after implantation. Additionally, MSCs injected intravenously also migrated to the lesion site and were visible for 7 weeks post-implantation. Similarly, MSCs injected intravenously also migrated to the lesioned spinal cord, which was also confirmed with Prussian blue staining.

Thus, the use of stem cell therapy to treat neurodegenerative diseases is a realistic possibility in the near future. However, the need for non-invasive imaging techniques is a prerequisite in order to monitor these transplants to determine clinical efficacy. Examination by MRI ensures that the stem cells are not only injected to the lesion site, but it also allows the monitoring of inappropriate cellular migration, and furthermore identifies damage to surrounding tissues.

MRI Tracking of Cell-Based Tumor Therapy

Cell-based therapies have received much attention as novel therapeutics for the treatment of cancer [2]. For example, tumor antigen-specific lymphocytes have been used for adoptive transfer and treatment in lymphoma, melanoma, and other malignancies. But a major obstacle to an accurate evaluation of treatment efficacy and anti-tumor effects has been the inability to track these cytotoxic T-lymphocytes (CTLs), *in vivo* at sufficiently high spatial and temporal resolution [96]. Dodd *et al.* [97] demonstrated the distribution of T cells labeled with CLIO-TAT peptide, by *in vivo* MRI, in mice following intravenous administration. These studies also showed the migration of T cells loaded with CLIO-TAT to the spleen by monitoring a decrease in signal intensity observed by MRI at 4.7 T. Similar protocols have been used to detect the localization of cells in small sites such as tumors and lymph nodes in small animals.

Kircher *et al.* [98] were the first to assess and quantitate the recruitment of systemically administered cells over time in a model of melanoma. They used an improved superparamagnetic particle (CLIO-HD: highly derivatized CLIO nanoparticles) to optimize the lymphocytes labeling at levels that can be detected *in vivo* via high resolution three-dimensional $T2$-weighted MRI at 8.5 T. This study showed the ability to examine both cellular recruitment and therapeutic response (tumor volume change) in three dimensions, across the entire tumor simultaneously, and in quantitative and repetitive manner in the same animal using MRI.

Zhang *et al.* [99] have reported the *in vivo* targeting and infiltration by magnetically labeled neural progenitor cells, derived from the adult SVZ, to a tumor mass in a rat model of gliosarcoma. To date, this was the first study in which adult neural stem cells have been employed to target a brain tumor. The non-invasive imaging, by MRI at 7 T, monitored the dynamic migration of superparamagnetic particle-labeled neural progenitor cells toward the brain tumor. Indeed, the spatiotemporal distribution of transplanted cells and the tumor in the host brain identified by MRI was confirmed using histochemical staining and fluorescent microscopy. This study also demonstrated, using MRI, the migration of iron oxide nanoparticles labeled MSCs toward the tumor, thus confirming previous reports of stem cell infiltration of brain tumors [100,101].

Development of MRI techniques for *in vivo* assessement of the interaction between grafted neural progenitor cells and tumor cells in the host brain may contribute not only to our understanding of the mechanisms involved in the treatment of brain tumors with neural progenitor cells therapy but also assess the outcome of neural progenitor cell therapy both in animals and in humans with brain tumors.

Tumor vasculature has attracted much interest as a potential target for cancer therapy [102]. Since cancerous growth depends on a good blood supply for nutrition and oxygen, the ability to image tumor vasculature would help to monitor the progress of cancer therapies. Brown *et al.* [103] demonstrated the accumulation of Sickle red blood cells (RBCs) in tumor vasculature, using MRI at 7 T. In this study, RBCs, from patients with sickle cell anemia, were loaded with Gd-DTPA and injected intravenously in rats with 9L glioma. $T1$- and $T2$-weighted MR images were used to monitor the infiltration of Gd-DTPA-loaded RBCs into the tumor mass. Additionally, changes in hemoglobin–oxygen state after administration of RBCs, without Gd-DTPA loading, was assessed using BOLD imaging. MRI allowed the visualization of the preferential aggregation of RBCs in tumor periphery.

Thus, MRI can be used as a useful technique to follow the cellular migration and recruitment to monitor the progress of cell-based therapy in tumors.

The high anatomical resolution together with the non-invasively *in vivo* imaging methodology offered by MRI, applied to monitoring implanted cells, will greatly facilitate the clinical realization and optimization of the opportunities for cell-based therapies. There are numerous examples where similar methodologies of cell tracking can aid in clinical diagnosis or can be used to trace other cells types, such as those following an inflammatory response [104,105].

Part I, Section 3:
Applications in Marine Science

Foreword to Applications in Marine Science

Today, strong focus on freshness and high product quality is an essential strategy of fisheries and aquaculture. Both consumer and marked are becoming nowadays increasingly aware of all the dietary benefits of marine foods for human health. Maintaining the quality of marine foods through the whole value chain is one of the most important challenges for this industry. Therefore it is necessary to develop basic knowledge about the product composition, degradation processes, effects of processing on product shelf life as well as effective methods of quality preservation. Much of on-going research in being carried out in this field, where both traditional and more sophisticated techniques are in use. Modern Nuclear Magnetic Resonance (NMR) technique is a unique method that opens up great possibilities to study foods non-destructively and non-invasively in many different ways.

In the first part of the section the application of several **low field NMR techniques** for use in process and quality control is demonstrated. One of them is a newly developed time domain NMR technique allows determining the most important quality parameters of fish feed as protein, carbohydrate, fat and moisture content in one measurement. This application is implemented as an at-line method in several fish feed production plants. Furthermore, the low field NMR techniques can provide with information about the fat and water in fish tissue, and a combination of the free-induction decay and the pulsed gradient spin-echo technique allows simultaneous determination of fat and water content in fatty fish species. It is shown how the structural changes in fish muscle, water binding and distribution within the muscle can be studied by the low field NMR. The available mathematical methods for extracting the information from the NMR relaxation signals are discussed as well. A great potential of the low field NMR as a user-friendly non-destructive method for measuring of important quality attributes in marine foods is demonstrated.

The second part of the section deals with the **high resolution NMR.** It is shown to be a unique tool in lipid research, where many metabolites and components can be studied simultaneously in relatively short time without any extraction involved. High resolution NMR enables to quantify lipid classes, to obtain fatty acid composition, to study the positional distribution of fatty acids in the triacylglycerol molecule, as well as to study the lipolysis and lipid oxidation in the same sample. Utilization of various Electron Spin Resonance (ESR) techniques is also shown to provide an additional valuable information regarding early stages of lipid oxidation in marine material.

The third section presents the use of **^{1}H and ^{13}C high resolution magic angle spinning (HR MAS) NMR** for quantification of the total omega-3 fatty acids in intact muscle of salmon. Application of this method for metabolic profiling of micro algae and analysis of fatty acids and storage polysaccharide structure in algae is presented as well. Ability to perform spectroscopic NMR investigations on intact cells or muscle allows to obtain a vast amount of information in a truly non-destructive way on, for example, degradation processes or biochemical processes related to fatty acid biosynthesis. Another important practical benefit of the HR MAS NMR is that both ^{1}H and ^{13}C experiments can be done on the same sample with only one simple sample preparation.

In the fourth section the use of the **Magnetic Resonance Imaging** (**MRI**) as research tool in food science is demonstrated. Due to high investment costs, the sheer size of the instruments and the infrastructure needed, MRI can not presently be introduced as a standard analytical tool in aquaculture or fish processing industry. However, as a research tool taking advantage of the unique features of the method, one can obtain basic insight into a number of issues related to anatomical studies, composition and structure of tissues, distribution maps of fat, water and salt as well as temperature profiles. In some cases theoretical transport models can be used to interpret the images, like for example in MRI studies of salting or dehydration. MRI has a great potential for fish industry as a tool to study the effects of feeding regimes during the fish on-growth phase and breeding, optimisation of unit operations in the fish processing such as salting, freezing and thawing.

Introduction

The quality of fish feed and the effectiveness of fish feed production process are important issues for both fish feed suppliers and fish farmers. A correct combination of protein, carbohydrate, fat, and moisture contents in fish feed is crucial for achieving a desirable growth rate and other key characteristics of farmed fish.

Ability of fast at-line control of the composition of fish feed would give fish feed producers an advantage of more flexible control over the production, resulting in a more effective consumption of energy and raw ingredients, increasing the production speed, and improving the quality of the final product. Ability to do rapid corrections in the ongoing production, based on the at-line analysis results would substantially reduce the amount of rework and low-grade production.

At the initial stage of fish feed production, a mixture of raw ingredients is prepared to produce the semi-solid matrix of the pellet. This mixture of raw ingredients mainly contains protein, carbohydrate, moisture, and fat. During the extrusion process, this mixture is compacted under high temperature and pressure to form a pellet with a porous, semi-solid wet matrix. The pellet matrix is then dried and saturated with fish or vegetable oil.

Wide variety of well-known analytical procedures currently adopted by feed producers for compositional analysis of fish feed has a number of common disadvantages. These standard chemical–physical tests are usually time consuming, demanding highly trained staff, costly, most of the standard methods are destructive for the sample, often require thorough calibration, many of them utilize dangerous toxic solvents and cannot be performed at the production line.

To the contrary modern time domain nuclear magnetic resonance (TD NMR) analyzers offer a wide spectrum of quick, non-destructive, and precise applications. Thanks to the high automation of modern NMR instruments, most routine tests can be performed by the ground-floor personal. A TD NMR instrument can perform a number of experiments, providing with various types of information about the studied material. This is accomplished by programming and running specific NMR pulse sequences, such as, for example, "free induction decay" (FID), "Hahn echo" [1], CPMG [2], "solid echo" [3], and others. Choice of the NMR pulse sequence depends not only on the type of the information required, but also to a large extent on the physical and chemical properties of the sample. Presence of solid and liquid phases, their mobility, rigidity, and NMR relaxation times are the most important parameters to be taken into consideration.

A number of TD NMR applications have recently been developed and adopted for quality control of foods such as rapid determination of fat content in meat [4,5], characterization of fat and water states in cheese [6], prediction of the content of water, oil, and protein in rape and mustard seeds [7], solid fat content analysis [8], monitoring of textural changes in frozen cod [9], and NMR relaxation time studies of intact fish flesh [10] and meat [11].

Experimental

Equipment

The technique has been implemented on a BRUKER minispec mq10 TD NMR analyzer (Bruker Optik GmbH, Rheinstetten, Germany) using a built-in programming language ExpSpel [12]. The instrument operated at 10 MHz proton frequency and could accommodate sample tubes of 40 mm in diameter. Sample tubes could be filled up to about 4 cm filling height to be measured in the system. This corresponded to about 30 or more pellets depending on their size.

Fish Feed Samples

Fish feed pellet is a porous, semi-solid matrix saturated with fish oil. Fish oil content in a pellet typically varies within 16–40 wt.%. The matrix of the pellet consists of a number of chemical compounds depending on the recipe used in the production. The most important of them are protein and carbohydrate, that together usually constitute over 95% of the solid matrix weight. Other typical ingredients of the matrix are ashes, minerals, vitamins, and pigments. In addition the solid matrix of fish feed contains certain amount of rest moisture left after drying of the extruded pellets. Amount of the rest moisture can vary within 5–10 wt.%.

NMR Measurements of Fat and Moisture

In a fish feed pellet, the residual moisture is always strongly bounded to the solid matrix which makes its NMR relaxation time much shorter than that of the oil. This has been confirmed by a T_2 relaxation curve measurement by a CPMG technique with the following experimental parameters: echo time (TE) = 0.1 ms, relaxation delay (RD) = 2 s, number of acquired even echoes 8000, and number of scans 32. Figure 1 shows the continuous distribution of the T_2 relaxation times that was calculated by inverse Laplace transform algorithm [13] implemented in the BRUKER minispec software. From the last figure, it is seen that the average relaxation time of the residual moisture (peak centered at 3.5 ms) is much shorter than that of fish oil (peak centered at about 130 ms). The relaxation peaks in Figure 1 were additionally broadened by the processing. Close inspection of the measured relaxation curve indicated that there is no contribution of the moisture signal at times above 6 ms. Thus it was possible to quantify the total amount of hydrogen atoms present in the fish oil by a "Hahn echo" experiment with the echo time of 6 ms. Unlike the "Hahn echo," the amplitude of the FID signal from fish feed is proportional to the total amount of protons in the liquid phase, i.e. both fish oil and rest moisture. Thus by combining measured amplitudes of the FID and the "Hahn echo" signals both fat and moisture contents could be quantified.

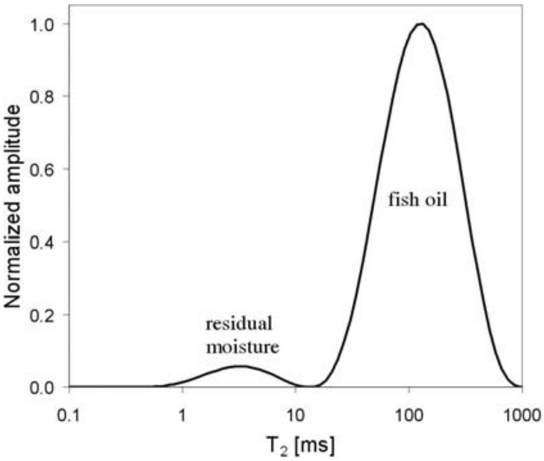

Fig. 1. Continuous distribution of the spin–spin relaxation times in fish feed.

NMR Measurements of Protein and Carbohydrate

Detection of NMR signal from large and immobile molecules like solid proteins has always been a challenging experimental task. These large molecules have extremely short NMR relaxation times and the majority of TD NMR techniques cannot be used for quantitative measurements of solid protein content. To obtain an NMR signal from the solid matrix of fish feed, a "solid echo" technique was used that allowed to overcome the receiver "dead time" problem and recover the full signal amplitude from the sample's solid part. The corresponding NMR sequence consists of two 90° pulses with different phases allowing to observe "solid" echoes from a system with dipole–dipole coupled protons [14]. If the sample contains both solid and liquid phases, the "solid echo" pulse sequence will in addition generate a FID-like tail following the "solid echo" signal [15]. This is schematically illustrated in Figure 2. In a fish feed production up to five main raw ingredients (fish meal, wheat meal, wheat gluten, soybean meal, and maize gluten) are mixed together in various proportions. Chemical composition of each raw ingredient of fish feed is always known from the preliminary wet chemical analysis. The total amplitude of the observed "solid echo" is a measure for the total amount of all protons in both solid and liquid phases of the sample. The difference between the total "solid echo" amplitude and the FID amplitude originates only from the solid part of the sample as indicated in Figure 2. The solid matrix of fish feed consists mainly of proteins, carbohydrates, ash (<10%), vitamins (<1%), and pigment (<0.1%). In order to extract the NMR signal due to the protein content of fish feed only, a set of five "protein" coefficients, one for each raw ingredient, was introduced. The coefficients represented parts of the "solid echo" signal due to the protein contribution for each raw ingredient relative to that of pure fish meal. Fish meal was thus assumed to be a reference ingredient having a "protein" coefficient equal to 1. The calculation of the protein content

in unknown samples uses only relative to each other values of the "protein" coefficients and the choice of the reference ingredient was arbitrary. The "protein" coefficients were calculated (Figure 3) on the basis of the measured "solid echo" amplitude from each raw ingredient and their protein content known from the chemical analysis. Therefore, the amplitude of the "solid echo" for each raw material corrected with its corresponding coefficient lay on a straight calibration line, as shown in Figure 3.

Knowing the recipe of each produced fish feed batch and using the respective "protein" coefficients for the raw ingredients used, it was then possible to extract the protein signal from the total measured "solid echo" signal for the fish feed as well. The method obviously assumed that the recipe was preserved all the way from the dry mixture of raw ingredient to the ready fish feed, i.e. that the relative amount of each ingredient in the fish feed solid matrix was the same as it was in the dry mixture. Determination of the carbohydrate content was accomplished in a similar way.

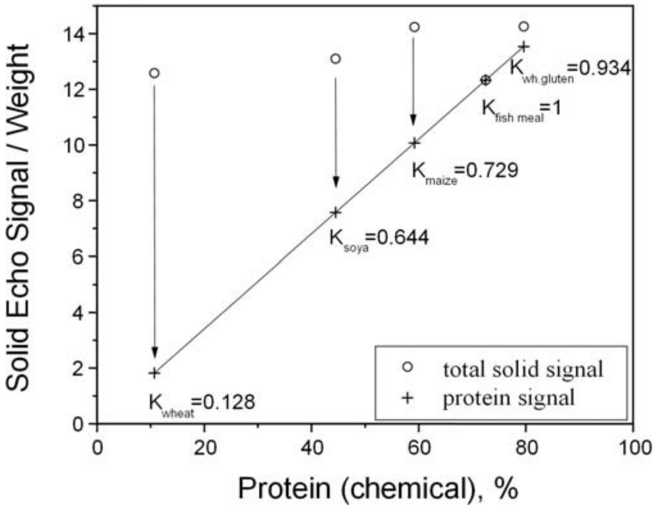

Fig. 3. Principle of calculation of the protein "coefficients" used to extract the protein originated part of the measured "solid echo" amplitude.

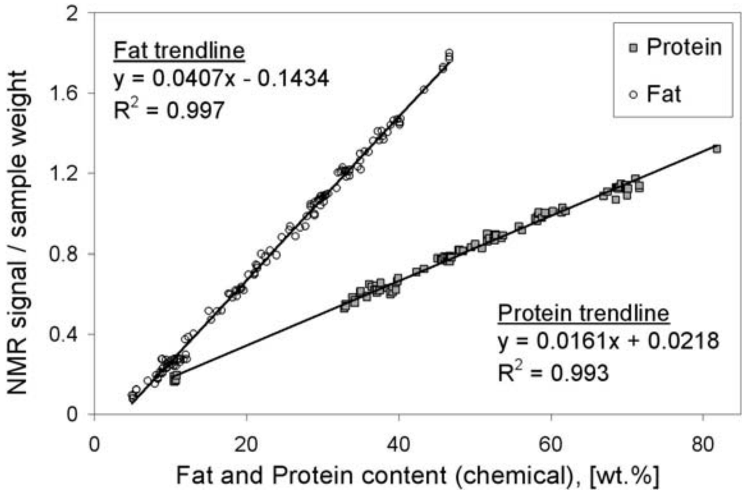

Fig. 4. Calibration curves for protein and fat contents determination.

Chemical Analysis

Following chemical analysis methods were used to produce the reference protein, carbohydrate, fat, and moisture contents data in the raw ingredients and the fish feed samples: the protein content was determined by a standard Kjeldahl method [16], fat content—by standard fatty acid hydrolysis method [17], the rest moisture—by weight change after drying [18] and the ash—by standardized burning in furnace [18]. Carbohydrate content has been calculated as follows:

Carbohydrate (wt.%) = 100% − [fat + moisture + protein + ash](wt.%), where fat, moisture, protein, and ash are chemically determined corresponding reference values in weight percent.

Calibration

Prior to the measurements, the NMR instrument had to be calibrated with a set of reference samples. The protein, carbohydrate, fat and moisture content in these samples were determined chemically beforehand. For protein and carbohydrate calibration, the reference sample set had to contain the raw ingredients as well. Prior to calibrating with fish feed samples, the application had to be calibrated against samples of raw ingredients in order to find the correct "protein" and "carbohydrate" coefficients for all the raw ingredients. During the calibration four types of NMR signals (protein, carbohydrate, fat plus moisture, and fat) were measured, normalized with the sample weight and plotted vs. the corresponding chemical values. Totally 100 samples were used for the protein calibration curve, with the protein content ranging from 10.4 to 81.8 wt.% and 47 samples for the carbohydrate calibration. The cumulative fat plus moisture calibration curve and the fat calibration curve were produced using 112 and 132 fish feed and raw ingredient samples, respectively, with the fat content ranging from 4.9 to 46.6 wt.% and moisture content from 4 to 16 wt.%. As examples, only the protein and fat calibration curves are shown in Figure 4 with the respective linear fit results.

A routine for transferring of the existing calibration data from one NMR instrument to another has also been implemented into the application, such that only a few (normally 3 or 4) reliable reference samples are used to adjust the existing calibration curves on a new NMR instrument. This procedure takes only a few minutes to accomplish, giving a possibility to quickly reproduce nearly identical calibration curves on different instruments.

Results and Discussion

In order to check the performance of the TD NMR method the protein, carbohydrate, fat, and moisture contents in 12 fish feed samples were determined with both the TD NMR technique and the reference chemical methods. Correlation plots between the NMR and the reference chemical methods are shown in Figure 5 demonstrating good correlation between the techniques. Statistical analysis of the agreement between the methods is given in Table 1, demonstrating good performance of the NMR technique compared with the standard chemical

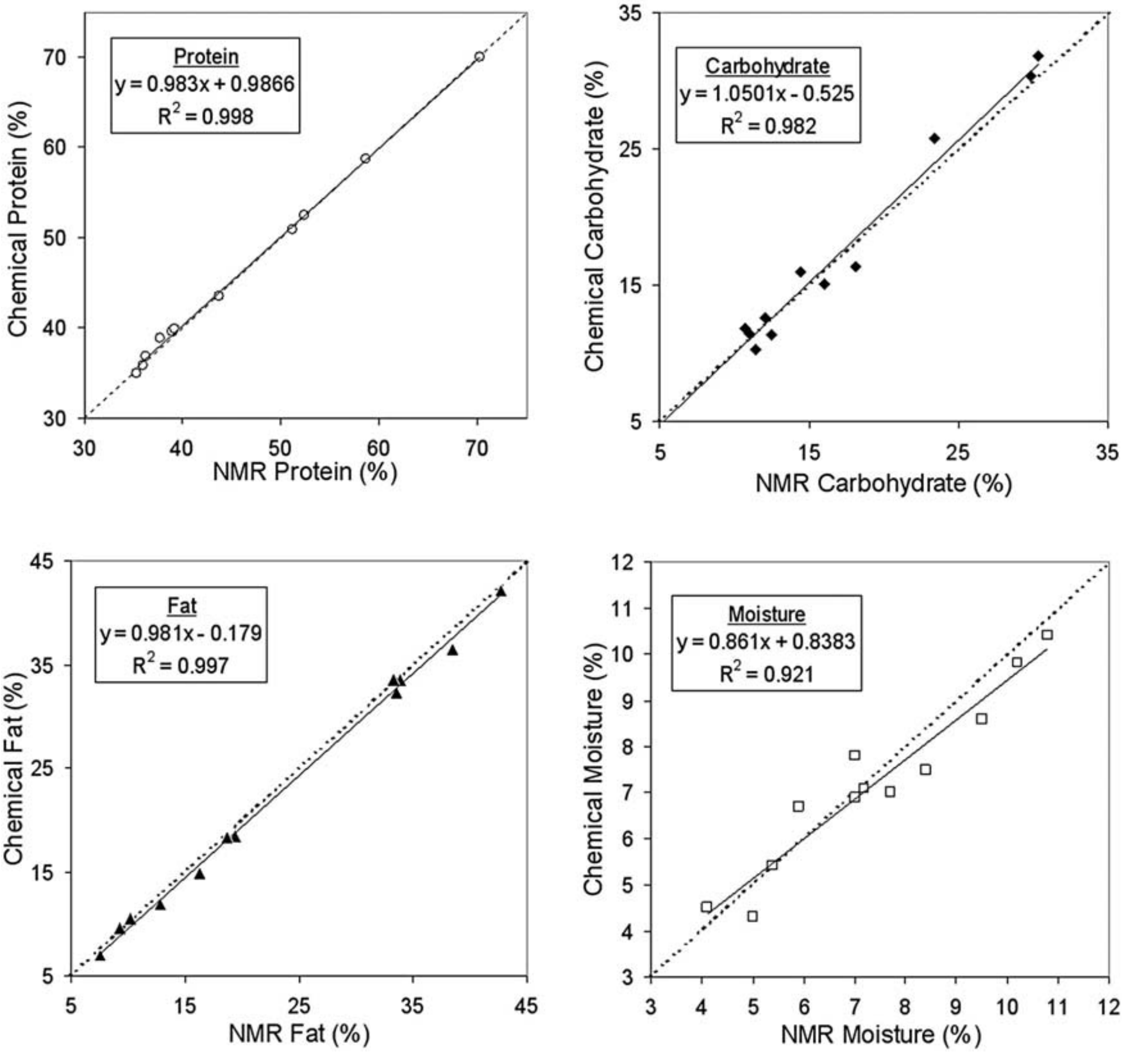

Fig. 5. Correlation plots for protein, carbohydrate, fat, and moisture content in 12 fish feed samples: the TD NMR vs. chemical analysis.

Table 1: Statistical analysis of the agreement between the NMR and the reference chemical methods

Measured quantity	Average standard deviation of the differences	95% range of agreement (±2SD) MIN	MAX	Correlation coefficient R^2
Protein	−0.2	−1.2	0.8	0.998
Carbohydrate	−0.3	−2.9	2.3	0.982
Fat	0.6	−0.8	2.0	0.997
Moisture	0.2	−1.0	1.4	0.921

Table 2: Repeatability of the NMR measurements on a dry mixture sample

Dry mixture sample	Protein wt.%	Carbohydrate wt.%	Fat wt.%	Moisture wt.%
1	58.6	18.1	7.6	6.9
2	58.9	18.2	7.5	7.0
3	58.5	18.3	7.8	7.2
4	59.3	18.4	7.7	7.2
5	59.5	18.3	7.7	7.3

* calculated on a 95% confidence level

analysis. Repeatability of the NMR measurements has been checked performing a series of 10 repeated determinations on a dry mixture sample, showing very good repeatability as seen from Table 2. For the carbohydrate content, the correlation coefficient (0.982) was lower than that of protein (0.998) which is apparently due to the indirect calculation of the chemical carbohydrate values. Fat correlation plot shows good correlation (0.997) with a slight bias about 0.6% towards NMR fat values. This might indicate a general trend of standard chemical extraction to underestimate the total fat content in certain types of fish feed. Relatively low correlation for the moisture content (0.921) is probably a result of moisture content fluctuations in a semi-solid fish feed matrix being dependent on the humidity in the storage environment.

Along with the standard chemical analytical methods, the near infrared (NIR) spectroscopy is another established technique for the determination of chemical composition of fish feed and other foods [19]. Although modern NIR instruments can be used to analyze fish feed with good accuracy, there are several disadvantages of this technique compared to the TD NMR. A thorough comparative cost analysis clearly indicated a considerable reduction of annual running costs at a fish feed factory when using TD NMR in preference to NIR (EWOS Innovation Ltd, validation report, Dirdal, Norway, 2002). This mainly results from the fact that NIR instrumentation demands a continuous follow-up and recalibration due to high sensitivity of this spectroscopic method to the minor variations in the microscopic properties of the used raw materials.

To the contrary the TD NMR response is not sensitive to such minor variations in the raw materials used in the production being proportional only to the total quantity of the measured compound. Origin and type of fish oil and other raw ingredients do not have any significant impact on the observed NMR signals. Therefore, it is not necessary to recalibrate the instrument for new raw material batches that are supplied from different environmental sources. The latter is often the case in fish feed production.

NIR technique has a number of other drawbacks, which can make the NMR method to be preferred for routine fish feed quality control at fish feed factories. NIR technique is based on use of sophisticated mathematical models and multivariate data analysis, it often needs sample preparation and is therefore destructive and user dependent. Use of the NIR to analyze fish feed with high fat content (>36%) is usually associated with additional difficulties. This is due to the fact that grinding of such fatty samples produces highly reflective surfaces, which disturbs the spectroscopic measurement [19].

Conclusions

A combination of "solid echo," "FID," and "Hahn echo" NMR techniques implemented into a TD NMR analyzer can quickly and non-destructively provide information about the protein, carbohydrate, fat, and rest moisture content in fish feed. The estimated accuracies of the protein, carbohydrate, fat, and moisture contents determination are 1.0, 2.6, 1.4, and 1.2%, respectively, based on the comparison with the reference chemical analysis. The method has been successfully tested in a research fish feed factory (EWOS Innovation Ltd, Dirdal) and has proven to be quick, precise, and robust. The TD NMR technique has a potential to be implemented on-line for automated quality control of fish feed production.

TD NMR technique is quick and non-destructive. It utilizes no dangerous toxic solvents and can be performed by ground-floor personnel. The TD NMR equipment requires no maintenance. These obvious advantages make the NMR technique highly competitive with both chemical analysis and NIR. Main disadvantage of the presented method is that the determination of protein and carbohydrate contents relies on availability of the feed recipe.

The present TD NMR technique can be further modified and customized to determine similar quality parameters in other types of fodder and in a wide range of other dry products.

Acknowledgments

Bruker Optik GmbH (Rheinstetten, Germany) kindly provided the TD NMR equipment and software. The financial support of the company Leiv Eiriksson Nyskapning Ltd. (Trondheim, Norway) is gratefully acknowledged.

Introduction

Low field (LF) NMR spectroscopy (sometimes also called time-domain NMR) operates in the frequency range of 2–25 MHz. Being a bench-top instrument, it represents a simplified and cheaper version of a traditional NMR spectrometer. Nevertheless, the instrument can provide useful information about relaxation behavior and diffusion behavior. Moreover, the instrument can also be used in connection with at-line quality control for quick analyses of fat, water and protein. Unlike conventional chemical–physical analytical methods that may be time consuming and thus costly, the NMR technique is rapid and has low operation costs. Often, no sample preparation before analysis is needed, and chemicals that are potentially harmful to health and environment may be avoided. Unlike conventional NMR spectrometers equipped with strong superconductive magnets, LF NMR instruments have a relatively weak permanent magnet. Consequently, the instrument cannot resolve different spectral components in the frequency domain, i.e. the LF NMR technique can only deal with time-domain information. Data are collected by programming and running specific NMR pulse sequences such as free induction decay (FID) [1], Hahn-echo [1], Carr-Purcell-Meiboom-Gill (CPMG) [2,3], and solid-echo [4]. The choise of NMR pulse sequence depends on the desired type of information and on the physical and chemical properties of the sample. Presence of solid and liquid phases, their mobility, and rigidity are among the most important parameters to be taken into consideration. Assessment of proton relaxation behavior is a frequently used application of the LF NMR technique. Two types of relaxations can be identified, longitudinal (spin–lattice or T_1) relaxation and transversal (spin–spin or T_2) relaxation. The longitudinal relaxation is the re-establishment of nuclear magnetization along the main magnetic field direction after the system has been excited from energetic equilibrium by irradiation of radio frequency (RF) energy. The transversal relaxation is observed as the loss of net magnetization in the plane transversal to the main magnetic field direction and is a result of the loss of the phase coherence within the ensemble of nuclei in time. The transversal relaxation times are more rapid to measure than the longitudinal ones. Typical data acquisition times for pure aqueous solutions are about 3 and 40 min, respectively. Due to this, and because transversal relaxation data may contain more information, sometimes only transversal relaxation data are reported. For instance, transverse relaxation may be preferred since it is more sensitive to protein unfolding (denaturation) than longitudinal relaxation [5].

In muscles, at least two ordered water phases exist [6,7]. Thus, at least two different proton transversal relaxation peaks should be possible to identify, which indeed is also the case. These are sometimes denoted T_{21} at about 40–60 ms and T_{22} at about 150–400 ms. In addition, a minor peak may be observed at about 1–10 ms [8,9]. To detect the shortest transverse relaxation component, a short ($\tau \sim 12$ μs) interpulse spacing is required [10].

Depending on how the relaxation data are processed, quantitative prediction can be enhanced [11] or the number of observed relaxation peaks may be affected [12]. The relaxation time of free water is about 2500 ms. The observed relaxation behavior is associated with protons in water molecules being small and mobile. In general, the following "rule" applies—the higher the mobility of the protons (molecules), the longer is the relaxation time. For example, interactions of water with macromolecules will reduce relaxation times. The interpretation of T_{21} and T_{22} is somewhat controversial. A simple model has been put forward suggesting they represent intra- and extracellular water, respectively [13] whereas the shortest relaxation component (1–10 ms) is attributed to water tightly associated with macromolecules [8]. Alternatively, in meat it has been suggested that the T_{21} represents water located within highly organized protein structures and the T_{22} represents drip loss [9]. From this, we realize that by studying relaxation behavior, we can indirectly obtain information related to the microscopic structure of tissues. In systems with a high fat content, the interpretation of relaxation spectra may be more complicated due to the fact that the fat and water "peaks" may overlap (T_{22} peak) [14]. Altogether, the LF NMR technique may be considered a useful tool to, for instance, evaluate product and quality related changes occurring as a result of fish processing and subsequent storage such as chilling, freezing,

Graham A. Webb (ed.), Modern Magnetic Resonance, 905–913.
© 2008 *Springer.*

marinating, salting, heating, pressure treatment, modified atmosphere packing, etc.

A number of post-mortem studies of meat using LF NMR have been conducted. Fish has been less studied, and a summary is presented here. Frozen storage, heating, and pressure treatment of intact cod (*Gadus morhua*) results in the appearance of an additional relaxation component (>250 ms) thought to be associated with water exudation. The T_2 values increases with increasing temperature and duration of frozen storage, or with increasing temperature during heating [10]. In contrast, Jensen *et al.* [12] reported that cod relaxation times are not affected by frozen storage temperature or during subsequent chilled storage in modified atmosphere. However, the relative size of the water pools is affected. By applying a three-way chemometric method, four first-order relaxation curves are identified at 37, 56, 126, and 361 ms. Rather than analyzing intact samples, the fish in this study were minced before analysis. However, it should be noted that whole, minced, and homogenized pork muscle all exhibit the similar three component T_2 relaxations with no significant differences in the T_2 values [9]. Steen and Lambelet [15] showed that proton transverse relaxation experiments can be used as a tool to monitor texture changes occurring in cod mince during frozen storage. Three T_2 components were detected at about 0.7, 32–46, and 132–224 ms after 2 and 4 months storage. The storage temperature (-10, -20, and $-70\,^\circ$C) has a clear influence on the latter two relaxation components. In particular, the longest relaxation times decrease with decreasing storage temperature indicating lower water mobility as the fraction of frozen water increases. Moreover, these observations are significantly paralleled by texture changes (Instron measurements) in the mince during frozen storage. Water mobility and distribution of water in intact samples of cod were studied by Andersen and Rinnan [16] after ice storage for 5–7 days. Transverse NMR relaxations were analyzed using a multivariate technique (SLICING). Two water populations were identified with T_2 values of 50 and 94 ms. The shortest relaxation time is the dominating one measured near the head region, whereas the longest one is primarily observed near the tail region. As the water content increased going from head to tail, the effect was thought to be due to smaller muscle cells and fibers in the tail region affecting water pool distributions. Moreover, the amount of water in one pool correlates well ($R = -0.94$) with the overall water content. Furthermore, it has been demonstrated that by using LF NMR, the water-holding capacity of intact cod flesh can be predicted ($R^2 = 0.9$) over the range 30–90% [14]. In a study of salting and desalting of intact fresh and frozen-thawed cod fillets, the proton relaxations exhibit strong correlations with fillet pH, water-holding capacity, and salt content depending on data processing of relaxation curves. The T_1 and T_2 relaxation times significantly increased in fresh fish from 206 and 50 ms to 238 and 70 ms after brine salting, and to 274 and 94 ms after dry salting and subsequent rehydration, respectively. In the case of T_{21} and T_{22}, only T_{21} changed significantly after processing increasing from 45 ms in fresh fish to 69 ms in brined ones. The T_{22} values were around 124 ms were not affected by fish processing [17].

Jepsen *et al.* [14] demonstrated that by using LF NMR combined with chemometrics it is possible to determine fat (mean value 17.8%) and water (mean value 60.9%) in intact Atlantic salmon (*Salmo salar*) flesh. In a 5 kg fish, the highest fat content (40%) was found at the front part of the belly, whereas the lowest (5%) found was in the tail region. To determine total fat and water contents in minced meat, Sørland *et al.* [18] proposed a LF NMR method that does not require sophisticated post-handling of experimental data. Only a single-point calibration routine is necessary (100% oil). To resolve fat and water signals, a multipulsed magnetic field gradient spin echo (m-PFGSE) sequence can be used.

Studies of protein denaturation [5], simultaneous determination of water, oil, and protein contents [19,20], and analysis of solid fat content [21] are other examples of LF NMR applications that might be of interest in fish processing.

Traditionally, LF NMR studies have been performed with stationary magnets having homogeneous magnetic fields. Typical bore sizes range from 10 to 50 mm in diameter. Studies of larger objects, such as whole fish, are thus impossible. To circumvent this restriction, a new type of LF NMR instrument—the *minispec* Bruker Professional MOUSE®—has been developed. Using a mobile mouse probe as an alternative to a stationary magnet, samples unrestricted in size can be analyzed. On fish, the method has been used for determination of fat content in live Atlantic salmon [22].

The goal in the current studies was to demonstrate some LF NMR applications relevant for the fish processing industry.

Materials and Methods

NMR Instrumentation

Two types of LF NMR techniques were used in the present study—a stationary and a portable NMR analyzer. The stationary LF NMR analyzer was the minispec mq 20, (Bruker Optik GmbH, Germany) with a magnetic field strength of 0.47 T corresponding to a proton resonance frequency of 20 MHz. The instrument was equipped with a gradient unit capable of delivering gradients of up to 3.6 T/m and a 10 mm probe. The temperature in the probe was regulated by blowing compressed air through the sample holder and a built-in heating element connected to the temperature control unit (VT3000®, Bruker Optik GmbH).

The mobile NMR probe—the Bruker Professional MOUSE(Bruker Optik GmbH)—was connected to the instrument mentioned above, i.e. in place of the stationary magnet. The mobile NMR analyzer is suitable for measurements in the near surface volume of samples unrestricted in size. The instrument has a magnetic field strength at the probe surface of 0.35 T and a permanent magnetic field gradient of about 10 T/m. The main magnetic field (B_0) is generated by two anti-parallel polarized permanent magnets. A surface coil is mounted in the gap between the magnets for transmission and detection of the RF signals. The measurement volume of the probe is about 5 × 5 mm in-plane and 2.5 mm in-depth and is determined by the strength of B_0, its inhomogenity and the bandwidth of the RF pulses. It is designed such that the first 5 mm from the probe surface do not contribute to the NMR signal. The measurement volume is thus located between 5 and 7.5 mm from the probe surface. A detailed design of the mobile NMR analyzer and the principles of it's operation are described elsewhere [23].

Fat and Water Analysis of Atlantic Salmon Homogenates Using LF NMR

Since the diameter of the NMR tube was 10 mm and the homogenous magnetic field area in the RF coil was about 5 mm high, the sample size was thus very restricted. Furthermore, the fat content in salmon muscle is not evenly distributed [24]. Consequently, to minimize the effects of sub-sampling, we decided to work with homogenates (rather than intact muscle samples) prepared from a larger muscle samples. In this way, the NMR fat analyses would be more comparable with those obtained from chemical extraction.

Fish and Sample Preparation

Three farmed Atlantic salmon (4.0, 4.1, and 4.2 kg) were bought at the local fish market 3 days post-mortem. Six wild-caught Atlantic salmon (gillnetted in the Namsenfjord, Central Norway), were divided in two groups according to size (1.8, 2.0, and 3.1 kg and 3.7, 4.0, and 4.1 kg). The fish were transported on ice to our laboratory where they were immediately frozen (−18 °C). After 1 month, they were thawed overnight in air (4 °C). Different sections of the left fillet from each fish were excised and homogenized (2–3 min) using a food processor (Braun Electronics, Germany). Totally, 54 homogenates were prepared (see Figure 5).

LF NMR Fat and Water Analysis

To determine fat and water contents in the homogenates a combination of two NMR techniques was used, a FID and a pulsed gradient spin echo (PGSE) sequence. The amplitude of the FID response was proportional to the total number of mobile ^{1}H nuclei contained in both fat and water molecules. The PGSE pulse sequence used magnetic gradients to suppress signals from the most mobile molecules in the sample, i.e. the water protons. Thus, the amplitude of the observed gradient spin echo was proportional to the amount of ^{1}H nuclei contained in fat only. To achieve full suppression of water signals rather strong gradient pulses were applied (3.6 T/m). The recycle delay (RD) was set to 2 s and 16 scans were accumulated. The measurements were performed at 22.5 °C.

A calibration routine based on the absolute weights (g) of fat and water was adopted. A commercially available homogenized salmon paste ("Havbris", Mills, Norway) with a declared fat content of 21% was used for calibration of the instrument. Different amounts of salmon paste were transferred into NMR tubes producing a set of 30 calibration standards with known fat content (range: 0.007–0.075 g) and different weights. The correlation coefficient of the corresponding fat calibration curve was $R^2 = 0.97$.

Similarly, only one water solution with known hydrogen index (relative volume density of hydrogen atoms—assumed to be one for pure water) was sufficient for the calibration. As calibration standards (seven NMR tubes), different amounts (range: 0.044–0.294 g) of distilled water doped with $MnCl_2$ (0.001 mol/l) were used. $MnCl_2$was added to shorten the T_2 relaxation time to a value similar to that commonly found in fish muscle (∼35 ms). The water content calibration was performed measuring the initial amplitudes of the FID signal from the calibration standards as a function of their respective absolute weights. The correlation coefficient of the obtained calibration curve was $R^2 = 1.00$.

The fat and water contents were determined by LF NMR. The samples (weight about 0.2 g; fat: $n = 26$; water: $n = 46$) were randomly picked from the 54 homogenates described above. The results were compared with Bligh and Dyer's fat extraction method and the sample dry weight (water content).

Chemical Fat Analysis

The fat content of the homogenates ($n = 26$), i.e. subsamples of the same homogenates analyzed by NMR, was determined in two replicates using the Bligh and Dyer method [25]. The results were correlated with those obtained from LF NMR measurements.

Water Content

The weight difference of the homogenates (about 2 g) before and after drying (105 °C, 24 h) was considered equal to the total water content of the sample. The mean value of two replicates is reported.

Fat Analysis of Atlantic Salmon Homogenates Using a Portable LF NMR Surface Analyzer (NMR MOUSE)

Fish and Sample Preparation

The homogenates ($n = 54$) described in the previous section were frozen in plastic bags for 4 months at -18 °C, thawed in air at 4°C and then thermostated in air to 20 °C for 1 h before analysis.

LF NMR MOUSE Fat Analysis

The fat content was determined using the Bruker Professional MOUSE. The technique relied on the fact that the measurement volume was constant for both calibration standards and homogenates. Therefore, the sample must always cover the entire RF coil area. The T_2 was measured at 20 °C using the CPMG sequence. The following instrumental settings were used: echo time (T_E) (time between the 90° and 180° pulse in the CPMG method) 300 μs, RD 0.2 s and 64 scans were accumulated. The fat signal was measured as an average value of 34 echo amplitudes between 15 and 25 ms of the CPMG echo train. Each measurement took about 20 s, and six parallel measurements were performed per sample. The calibration of the instrument was performed with a set of specially prepared samples with known fat contents and relaxation properties similar to fish muscle [22].

The fat content of 23 frozen-thawed homogenates (in plastic bags) was measured, and the NMR measurements were correlated with chemical fat extraction. The fat content of different fillet section homogenates ($n = 54$; 6 sub-samples per homogenate) of farmed and wild-caught salmon was also determined from the NMR MOUSE measurements.

Water Distribution in Intact Atlantic Salmon Muscle After Heating

Fish and Sample Preparation

A farmed Atlantic salmon fillet was bought at the local market 3 days post-mortem. Four samples (about 0.2 g each)—from both red and white muscle—were excised from the middle section of the fillet (below dorsal fin).

LF NMR Water Analysis

The samples were transferred to 10 mm NMR tubes without further preparation. The T_2 relaxation behavior was measured at 4, 20, 40, and 55 °C. Before each measurement, the samples were thermostated for 30 min in a water bath (Julabo F10, Germany) having the same temperature as in the NMR probe. The CPMG sequence with the following settings was used TE = 0.1 ms, RD = 3 s, and 16 scans with 5000 even echoes were accumulated. The obtained relaxation curves were inverted into corresponding distributions of relaxation times using the CONTIN regulation algorithm [26] implemented in the Bruker minispec mq software.

Diffusion Weighted Transversal Relaxation Measurements: Separation of Fat and Water in Atlantic Salmon White Muscle

Fish and Sample Preparation

A farmed Atlantic salmon fillet was bought at the local fish market 3 days post-mortem. Three parallel samples from the belly flap area were excised using a specially designed coring tool. The samples (about 0.4 g) were transferred to NMR tubes.

LF NMR Analysis

In conventional NMR relaxation spectra, it is not always possible to distinguish relaxation components even though their diffusion constants may be different. An example of a peak overlap in such spectra is the fat and "extracellular" water in fatty fish (salmon) muscle (the "T_{22} peak"). The CPMG sequence and a pulsed field gradient spin echo sequence were combined with a train of 180° refocusing pulses (Figure 1) made it possible to obtain a two-dimensional (2D) dataset of diffusion weighted transversal relaxation curves. The data were processed by the recently developed 2D Inverse Laplace Transform [27] implemented in the MatLab software package (The MathWorks Inc., U.S.A.) [28] producing a 2D diffusion vs. T_2

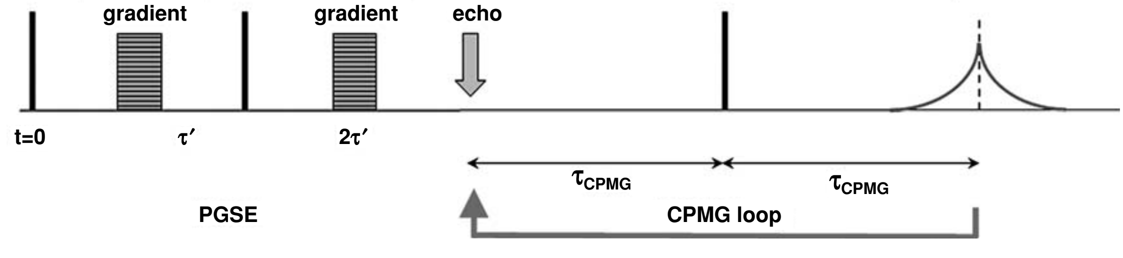

Fig. 1. The PGSE-CPMG pulse sequence used for producing a 2D diffusion/T_2 relaxation map, see Figure 8.

relaxation time distribution map. The method resolved a conventional one-dimensional (1D) T_2 distribution in the dimension of diffusion. Thus, it was possible to distinguish between mobile proton-containing compounds with (nearly) similar relaxation times, but with different diffusion coefficients.

A water bath (Haake UWK 45, Germany) was connected to the probe head to ensure a constant probe temperature of 25 ± 0.1 °C. Before measurements, the samples were thermostated 25 °C for 1 h in a separate water bath.

In the experiment, the gradient strength of the PGSE part of the sequence was incremented from 0 to 3.2 T/m in steps of 0.16 T/m. The CPMG part was acquired for each single gradient value producing a total of 21 diffusion weighted CPMG curves. The echo times (time delay between 90° and 180° pulses) were set to 20 (PGSE) and 0.2 ms (CPMG), RD was set to 2 s and 4000 even echoes were acquired in eight scans.

Results and Discussion

Fat and Water Analysis of Atlantic Salmon Homogenates Using LF NMR

The fat and water contents in salmon homogenates were compared using LF NMR vs. fat extraction and weighing after sample drying (Figure 2). In case of fat, the correlation was good ($R^2 = 0.94$). The NMR-based results were slightly lower than those obtained by chemical extraction. The water content of the same homogenates is shown in Figure 3. The correlation coefficient over the range 40–80% water was $R^2 = 0.84$. Thus, the proposed method may be used for rapid determination of fat and water contents in tissues. The sum of the mean fat and water contents was 76 ± 6%. Grossly speaking, in fatty fish species the sum of tissue fat and water is about 80%. Thus, our fat and water determinations seemed to be within the expected range.

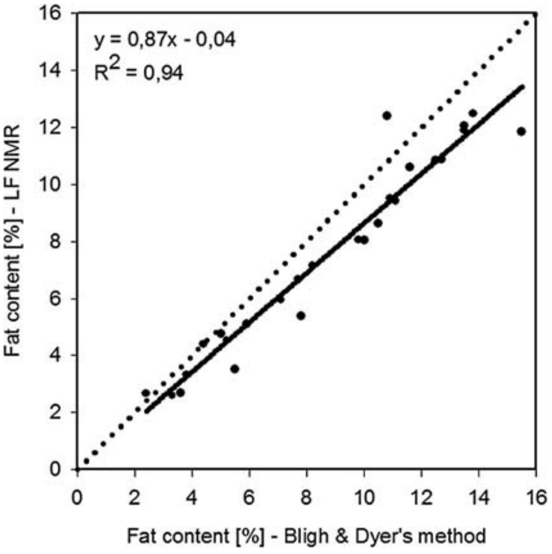

Fig. 2. Fat content in homogenized Atlantic salmon muscle as determined by LF NMR and chemical extraction methods ($n = 26$). The dashed line represents 1:1 ratio.

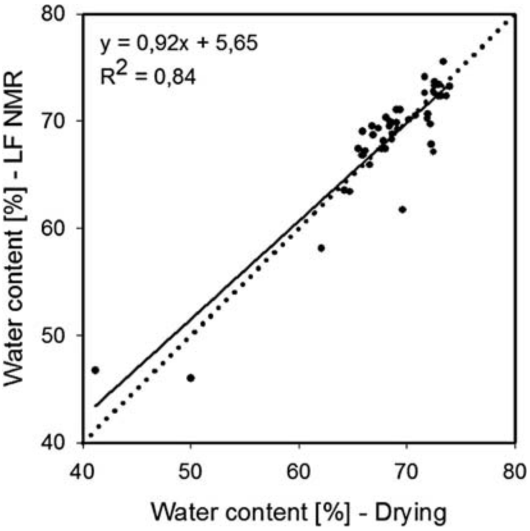

Fig. 3. Water content in Atlantic salmon muscle homogenates as determined by LF NMR and sample drying ($n = 46$). The dashed line represents 1:1 ratio.

Fat Analysis of Atlantic Salmon Homogenates Using a Portable LF NMR Surface Analyzer (NMR MOUSE)

The fat content of the homogenates (same batch) was also analyzed by NMR MOUSE and the results were compared with the chemical extraction method (Figure 4). The methods produced nearly similar results ($R^2 = 0.95$) indicating that the NMR method may be a useful tool for rapid non-invasive determination of fat. Therefore, with further development, the NMR MOUSE concept may have the potential for online applications. The correlation with Bligh and Dyer's fat extraction method was basically similar to that achieved with LF NMR ($R^2 = 0.94$). Veliyulin *et al.* [29] used the NMR MOUSE method to determine fat content in a population of live salmon. In this case, the

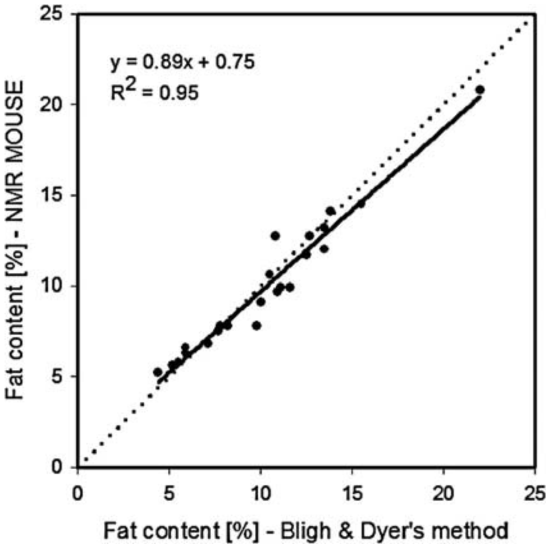

Fig. 4. Fat content in homogenized Atlantic salmon muscle as determined by NMR MOUSE and chemical extraction methods ($n = 23$).

method's correlation with the chemical extraction (Ethylacetate) method was also good ($R^2 = 0.92$).

The fat distribution in farmed and wild-caught salmon fillet was studied by NMR MOUSE (Figure 5). No significant differences between fat content in farmed and wild-caught salmon of approximately the same size (4 kg) was found. As expected, the fat content of the smaller wild-caught salmon (2 kg) was lower. In the white muscle of both farmed and wild-caught fish (fish weight 4 kg), the mean fat content was about 10%, whereas in the smaller wild-caught fish (2 kg) the mean fat content was about 6%. In the belly flap the mean fat contents were 30 (4 kg fish) and 25% (2 kg fish). These values were within what can be expected from previous studies of Atlantic salmon, e.g. 9.6% [24] (2.9 kg) and 17.8% (4.9 kg) in white muscle [30] and 46.4% fat (4.9 kg) in the belly flap [30]. The Norwegian quality cut (NQC) contained about 12 and 7% fat in the 4 and 2 kg fish, respectively. Comparatively, Einen *et al*. [30] reported a NQC fat value of 16.7% for a 4.9 kg fish.

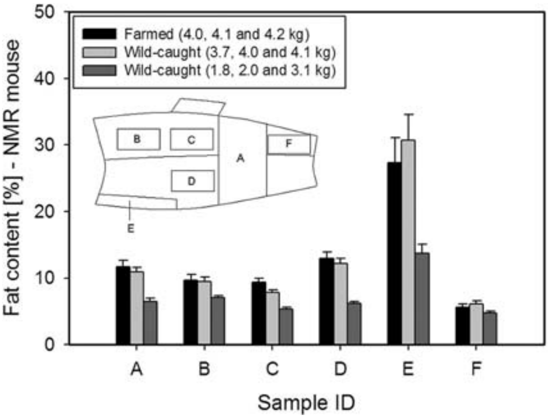

Fig. 5. Fat content in different sections of farmed ($n = 3$) and two groups of wild-caught ($n = 3$) Atlantic salmon. Each sample was subjected to NMR analysis six times. A = Norwegian Quality Cut.

Water Distribution After Heating of Intact Atlantic Salmon Muscles

To simulate the effect of heat processing of fatty fish muscles, transversal relaxation spectra of Atlantic salmon red and white muscles were acquired at 4, 20, 40, and 55 °C.

At 4 °C, the relaxation distribution in red muscle (Figure 6) exhibited four peaks at about 1 ms, 2–7 ms (T_{2b}), 20–110 ms (T_{21}), and 150–400 ms (T_{22}). Peaks in the same ranges have been observed in pork [9], cod [10,12–16], and Atlantic salmon [14]. The peaks at 1 ms and 2–7 ms exhibited merely minor changes with increasing temperature. Since the salmon red muscle has a high fat content, the T_{22} peak was—as mentioned above—associated with signals from both fat and water.

At 20 °C, the T_{21} and T_{22} peaks were shifted toward longer relaxation times indicating increased water mobility. When comparing the relative ratio between the two peaks at 4 and 20 °C, it is seen that the T_{22} peak increased. When increasing the temperature to 40 °C, dramatic changes occurred as the two peaks "melted together" into a hump. These findings are consistent with

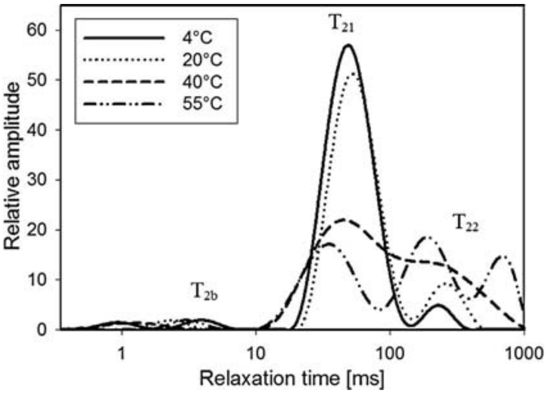

Fig. 6. Transversal relaxation time spectra of Atlantic salmon red muscle at 4 °C and after heating to 20, 40 and 55 °C.

those of Ogawa *et al*. [31] who studied the thermal stability of fish myosin using differential scanning calorimetry. They demonstrated that in case of rainbow trout (*Salmo gairdneri*), major structural changes (denaturation) occur at 25, 34, and 40 °C. Sano *et al*. [32] showed that carp actomyosin molecules began to unfold at about 30 °C, and at temperatures higher than 40 °C the myosin molecules are partly dissociated from the actin filaments. Moreover, Ofstad *et al*. [33] showed that upon heating of chopped salmon, a large loss of water occurs around 40 °C leading to structural changes, e.g. shrinkage of muscle fibers [34].

With further heating to 55 °C, the peak pattern changed again. Three clearly separated peaks appeared, approximately at similar signal amplitudes. Two peaks exhibited relaxation times corresponding to the "common" T_{21} and T_{22}, while a new peak appeared at about (400–1000 ms). Although being somewhat less mobile than at 4 and 20 °C, "the T_{21}-water" may still be related to water protein structures, although now partially degraded. The T_{22} peak may be associated with fat (and water). The water fraction (400–1000 ms) probably represents water becoming more mobile as a result of the major structural changes occurring in the protein matrix, i.e. expelled water (drip loss).

In white muscle (Figure 7), the distribution of water after heating was basically similar in several aspects to that of red muscle. Some differences were however observed. The T_{22} peak was smaller exhibiting higher water mobility (400–520 ms). The mobility of this water fraction decreased when increasing the temperature from 4 to 20 °C. At 40 °C, no hump was seen in this case. Instead, two well-defined peaks were observed at 13–60 ms and 130–480 ms, i.e. within the "common" T_{21} and T_{22} regions. With further heating to 55 °C, both peaks were shifted toward lower relaxation times, indicating reduced water mobility.

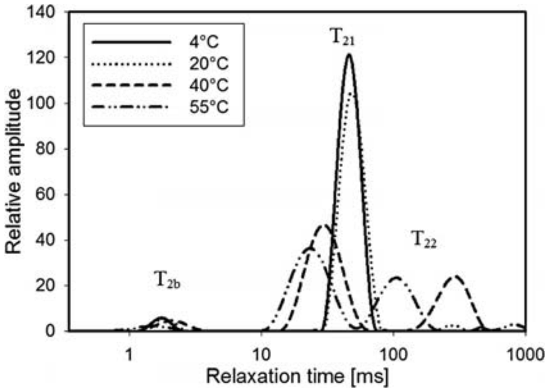

Fig. 7. Transversal relaxation time spectra of Atlantic salmon white muscle at 4 °C and after heating to 20, 40 and 55 °C.

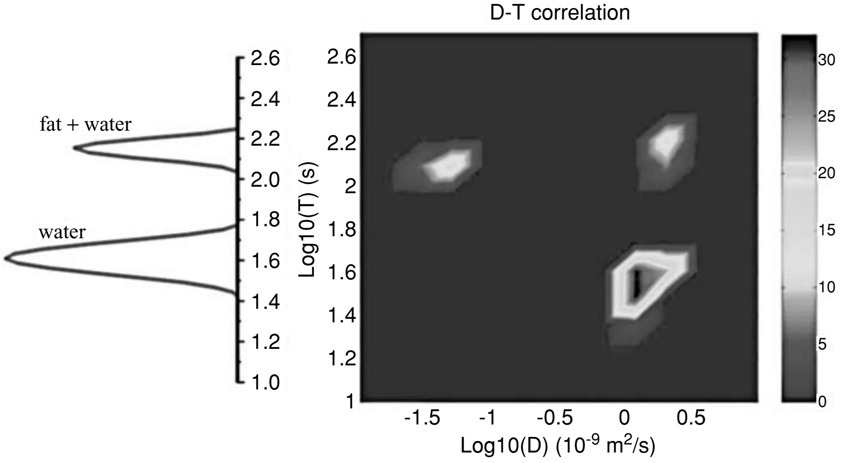
The observed differences in relaxation behavior are thought to be related to the difference in chemical composition of the two muscle types. Reported mean values of Atlantic salmon (3 kg) fat and water contents are 27.2 and 56.7% (red muscle), and 9.6 and 68.9% (white muscle), respectively [24]. In pork [35] and other foods, NMR relaxometry has commonly been used to determine the solid fat content. In contrast, due to the high amount of polyunsaturated fatty acids in Atlantic salmon [24], the mobile unsaturated fatty acids must be taken into consideration also at low temperatures. Regarding fat stability and mobility in this species, it has been reported that the fraction of total, unsaturated and saturated fatty acids stays essentially constant in the temperature range 0–40 °C [36].

To summarize, we have demonstrated that by using NMR relaxometry, several interesting features occurring as a result of heating can be observed. Protein denaturation can also be studied *in vitro*. For a better interpretation of the data, additional structural and compositional analyses are needed. Ultimately, such data may be useful to improve the heat processing of (fish) muscle-based raw materials.

Diffusion Weighted Transversal Relaxation Measurements: Separation of Fat and Water in Atlantic Salmon White Muscle

Continuous T_2 relaxation distribution maps do not fully separate water and fat in fatty fish tissues. This is because the "extracellular" water fraction relaxes with the same rate as fat [29] and only one single relaxation peak can be observed in a conventional 1D relaxation spectrum (between 100 and 200 ms; Figures 6 and 7). A new 2D technique overcomes this problem by additionally resolving the T_2 relaxation spectrum in the second direction of diffusion, making it possible to study the fat and water components separately. Figure 8a shows an example of a conventional transversal relaxation curve, while Figure 8b shows the T_2-diffusion map of Atlantic salmon white muscle. It can be seen that by using the 2D technique, "the extracellular" water fraction was clearly separated from the fat component. Regarding the relaxation peak at 140 ms, the advantage of the 2D distribution map approach compared with the conventional 1D is clearly seen. The 2D map clearly shows the presence of the two components around 140 ms, while the respective fat and water peaks completely overlap in the 1D distribution. The corresponding diffusion constants were 2.6×10^{-10} m^2/s (fat) and 2.0×10^{-9} m^2/s (water) as determined from the 2D distribution map. The water component at 140 ms probably corresponds to that observed in cod [10,12,14–16] and pork muscle [9], which is thought to represent extramyofibrillar water. For the major (intramyofibrillar) water component at $T_2 \approx 37$ ms, the



a) b)

Fig. 8. (a) A 1D transversal relaxation spectrum and (b) a 2D diffusion/T_2 relaxation map of intact Atlantic salmon white muscle. Arbitrary units. (See also Plate 81 on page LIV in the Color Plate Section.)

diffusion constant was $D \approx 2.0 \times 10^{-9}$ m^2/s. The method can be used as a diagnostic tool to assess possible fat–water overlap. In addition, quantitative information about diffusion constants and their corresponding transversal relaxation times can be obtained.

Conclusion

By using various LF NMR techniques, information about fat and water contents and their mobilities can be obtained. In turn, such information may be related to tissue structure changes occurring during fish processing. The portable LF NMR surface scanner (MOUSE) can be used to determine whole fish fat content. Introduction of a combined ^{23}Na and ^{1}H LF NMR probe would open up new possibilities for at-line quality control for rapid determination of salt, fat, and water contents in the fish (food) processing industry. Moreover, with the introduction of the NMR MOUSE concept, online quality control may be feasible in the future.

Water Distribution and Mobility in Fish Products in Relation to Quality

Bo M. Jørgensen, Kristina N. Jensen
Department of Seafood Research, Danish Institute for Fisheries Research, Technical University of Denmark, Lyngby, Denmark

Introduction

Water is the most abundant chemical substance in muscle-based food such as fish fillet, and the interactions between water and macromolecules are influential to various food quality attributes like texture and juiciness. Information on water binding and distribution within the muscle is therefore important while studying raw material properties and quality changes during processing and storage. Low-field NMR transverse spin relaxation of the water–hydrogen nucleus has been succesfully employed in food research to provide information such as the relaxation time, which is dependent on the mobility of the water molecule and thereby of its binding to or entrapment by structural elements of the cells.

In the present account, the available mathematical methods for extracting the above-mentioned information from the NMR relaxation signals are discussed. Examples from the literature are used to demonstrate how the water distribution can be related to raw material properties (fish stock, fat content), quality attributes (texture, water holding capacity) and changes during the processing and storage (protein denaturation).

Algorithms

The measured transverse relaxation curves, i.e. amplitudes or phase-rotated channel output from a CPMG pulse sequence, are most often mathematically well-behaved, consisting of a sum of mono-exponentially decreasing functions:

$$S_i(t) = \sum_{j=1}^{N} s_{ij}(t) = \sum_{j=1}^{N} m_{ij}\, e^{-k_j t} \qquad (1)$$

where $S_i(t)$ is the sampled measurement signal from sample i at time t, $s_{ij}(t)$ is the part of the signal originating from the component j, m_{ij} is the "amount" of component j in the sample, k_j is the reciprocal transverse relaxation time of component j and N is the number of separable components. Even in a highly heterogeneous system, like a muscle, a limited number of components or "pools" of the substance from which the signal stems (most often water) is identified, i.e. N is low (1–5).

In order to extract information related to water in the measured sample, one is normally interested in resolving the curves into the single functions $s_{ij}(t)$ and determine their parameters m_{ij} and k_j. An important exception is, however, mentioned below. Several algorithms exist, each with their own strengths and weaknesses. For the sake of this discussion, the algorithms are divided into two groups: those that operate on each sample separately and those that make use of multiple samples sharing a set of relaxation times.

Single-Sample Algorithms

The obvious (and classical) way to extract the function s from Equation 1 is by a simple exponential curve fitting. It is not straight-forward numerically, however, as the parameters are highly correlated and strongly dependent on the choice of the number, N, of components. The objective function, i.e. the sum of squared residuals, will always decrease with an increasing number of parameters, and the risk of over-fitting is high. The value of N has to be assumed without support from the data. These circumstances strongly suggest to the present authors that the simple exponential curve fitting method is inferior and must be avoided.

A more elegant way to deal with the measurement signal from a single sample is to consider m as a continuous function of k:

$$S_i(t) = \int_0^{\infty} m_i(k)\, e^{-kt}\,\mathrm{d}k \qquad (2)$$

with $m_i(k)$ having peaks at values k_j, $j = 1 \ldots N$ and being 0 elsewhere. The signal $S_i(t)$ thus is a Laplace transform of $m_i(k)$, which then can be found whenever it is possible to numerically calculate the inverse transform. A successful calculation results in a curve from which N is directly determined as the number of peaks, and k_j and $m_i(k_j)$ as the position and area of peak number j. But the result of the numerical calculation is extremely sensitive to noise and some sort of smoothing is mandatory. The

Graham A. Webb (ed.), Modern Magnetic Resonance, 915–918.
© 2008 *Springer.*

art is to make this smoothing balanced: strong enough to suppress noise and mild enough to avoid suppression of “real” component signals. A popular computer program, CONTIN, for solving integral equations like this one was developed by Provencher.[1,2] When the parameters of the algorithm have been set at values suitable for the actual measurements, the method is able to show systematic changes in relaxation times throughout a sample set, e.g. as a function of temperature or another variable of the experimental design.

Multi-Sample Algorithms

By making use of the full data set, i.e. the collection of measurement signals from several samples ($i = 1, \ldots, i_{\max}$) at the time, several new possibilities arise. Perhaps the most important is that the data themselves may provide a good estimate of N by issuing a warning when over-fitting is attempted. Using the signals $S_i(t)$ directly for calibration purposes is also a very useful option: partial least squares (PLS) regression models for prediction of quality parameters can be made, without having to extract the single component signals $s_{ij}(t)$ explicitly.[3–5]

In many cases, the single component signals are of interest, though. A proper use of the full data set then requires that the samples really are compatible in the sense that they contain common pools though in various relative amounts, i.e. the m-values, but not the k-values may differ significantly from sample to sample. When this prerequisite is fulfilled, exponential curve fitting (Equation. 1) may be performed by alternately fitting the set of non-linear parameters k_j and the set of linear parameters m_{ij} keeping the other parameter set constant. The method works well in practice though the calculation time increases fast with the number of samples.[6]

The most elegant multi-sample method used nowadays to extract the single component signals $s_{ij}(t)$ is parallel factor analysis (PARAFAC) of the data set made tri-directional. The data rearrangement may be done in many ways (cf. Pedersen *et al*.[6]); one that has proven efficient for measurements on fish muscle in our laboratory is thoroughly described by Jensen *et al*.[7] The procedure is a “soft-modeling” in the sense that the single-exponential functional form of s is not explicitly entered into the calculations (although obtaining a perfect tri-linear system, best suited for PARAFAC, requires this functional form). The result actually turns out to be a set of single exponentials (e.g. in Jensen *et al*.[7]) thus supporting its validity.

Determining the Number of Components

When using the full data set, several diagnostics exist by which the correct value of N may be estimated. A principal component analysis of the data matrix with elements $S_{it} = S_i(t)$ indicates how many independent variations exist not being purely due to noise. This number is an upper bound on N. Another efficient procedure is to split the data set between replicates and make the calculations on each subset separately. As long as over-fitting is avoided, the same set of single components should be extracted from each subset, as these differ only with respect to noise. When choosing the PARAFAC method, one may also look at the extracted components, which should be single exponentials. Noise components are not expected to follow this functional form, so the appearance of other forms is an indication of over-fitting.

Applications

The application of ^{1}H NMR on fish and fish products open the possibilities for relating the state and dynamics of water to various parameters, such as raw material properties, quality attributes, and storage and processing conditions. An overview of the applications described in the text is shown in Table 1.

Different raw material properties have been related to relaxation decays obtained by the CPMG pulse sequence. The potential of applying low-field NMR and multivariate PLS calibration for a fast and non-invasive determination of composition, i.e. lipid and water content, was explored in herring[8] and salmon.[3,4] The method was found to have low prediction errors, and furthermore demonstrated that it was possible to simultaneously determine lipid and water content[3,4] taking advantage of the inverse relation between water and lipid in fish muscle.[9] Low-field NMR was also used for mapping raw material differences, e.g. in relation to fishing ground, seasonal variations and biological parameters of herring caught in the waters around Denmark.[10] The unique decomposing of tri-linearized relaxation decays by PARAFAC showed that the number of water pools was depended on season of catch, whereas their variation between fishing grounds were related to differences in lipid content and spawning type (stock). In cod, the water distribution as determined by PARAFAC on tri-linearized NMR transverse relaxation decays was shown to depend on location in the fillet, which could be related to the size of muscle cells and fibres.[11] In mammalian muscle, *post-mortem* pH changes have been studied by low-field NMR transverse relaxation and related to changes in water characteristics during the conversion of muscle to meat in rabbit[12] and beef.[13] Although the *post-mortem* pH changes are smaller in fish, this method also seems to have potential for studying raw material properties in fish. In frozen systems, NMR could be used as an alternative method for determination of glass transition temperatures.[14] This possibility was also illustrated on pintado fish, where distributed T_2 relaxation time profiles were determined in the temperature interval from

[c] Meat samples heated prior to NMR measurements.

−50 °C to 30 °C revealing two abrupt changes in the water mobility.[15] In contrast to the traditional determination of glass transition temperatures by thermal analysis, the application of NMR offers the possibility of measuring actual molecule mobility rather than thermal events, which can be difficult to interpret.

Measuring quality attributes, such as water holding capacity (WHC) and texture, by low-field NMR using the CPMG pulse sequence have shown some promising results in the area of muscle food. Recent studies on cod have shown that WHC can be determined by multivariate PLS calibration of the relaxation decays.[4,5] In meat, continuous distribution analyses have revealed that areas of relaxation populations and corresponding time constant were highly correlated to WHC.[16] Another study on thawed cod mince showed that the longest relaxing component determined by exponential curve fitting was highly correlated to sensory and instrumental texture parameters as well as to the amount of dimethylamine produced during frozen storage.[17] These results demonstrate the great potential of using low-field NMR as a non-invasive method for measuring important quality attributes.

Changes in the water distribution and mobility during processing and storage of cod muscle, e.g. freezing and frozen storage, have also been studied by low-field NMR. Lambelet *et al*.[18] and Steen and Lambelet[17] showed that the NMR parameters as determined by exponential curve fitting were related to the freezing and frozen storage. In another study, the water distribution expressed as relative water pool sizes determined by PARAFAC on tri-linearized relaxation decays was shown to vary consistently with storage conditions, supporting the validity of the PARAFAC method.[7] Studies using magnetic resonance imaging (MRI) have also revealed that water distribution and mobility of cod, mackerel and trout are affected by freeze-thawing as quantitatively reflected in the MRI parameters.[19,20] In a study of salting and desalting of cod fillets, the relaxation time as determined by continuous distribution analysis of low-field NMR transverse decays was shown to be related to pH and the condition of the raw material, i.e. fresh or frozen-thawed.[21] Combination of low-field NMR and thermal analysis, i.e. differential scanning calorimetry (DSC), has shown that protein changes in cod due to different storage conditions are related to the water distribution.[18,22]. Rochdi *et al*.[23] studied the thermal denaturation of collagen from calf and cow muscle by measuring NMR transverse relaxation of preheated samples. Recently, food samples were heated directly in the NMR spectrometer with the process being followed by repeated low-field NMR transverse relaxation measurements, e.g. monitoring the dough-to-bread process, named NMR-baking.[24]. A similar procedure, named NMR-cooking, was used to follow the cooking process of meat.[25,26] On fish muscle, this method could offer an alternative approach for relating protein denaturation to changes in water state during processing.

Proton NMR of Fish Oils and Lipids

R. Sacchi,[1] M. Savarese,[1] L. Falcigno,[2] I. Giudicianni[3], and L. Paolillo[2]
[1]Department of Food Science
[2]Department of Chemistry and CIMCF
[3]University of Naples Federico II, Naples (Italy)

Introduction

In the last 10 years, high-resolution carbon-13 and proton-NMR spectroscopy have been successfully applied to the analysis of fish oils and lipids [1–10]. The purpose of these analyses was focused not only on the rapid determination of lipid classes and fatty acid composition but also on the assessment of positional distribution of fatty acids along the glycerol moiety, fish quality, lipid oxidation, and lipolysis. ^{13}C and ^{1}H-NMR are complementary techniques in order to define lipid composition and chemical alterations. ^{13}C-NMR offers the advantage of higher resolution but lack in sensitivity and requires longer time of analysis to obtain quantitative spectra. Proton NMR, on the other hand, is very rapid and quantitative, but proton signals of lipid molecules are present in a narrow spectral range thus reducing resolution. Therefore, different applications have been carried out taking into account advantages and disadvantages of two techniques.

^{1}H-NMR Spectra of Fish Oils and Lipids Extracted from Fish Muscles

F.D. Gunstone [1] in a pioneering work identified some of the lipid components in fish oils by attributing, in the proton spectra, several signals to polyunsaturated fatty acid (PUFA) components. The proton NMR spectra available in the literature for commercial fish oil [1], tuna lipids [4], salmon lipids [3], bonito and sardine oils [3,7] show similarities and differences, due to both the fatty acid profile of sample analyzed and to the lipid classes composition. NMR spectra of natural lipid extracts from fish muscles differ from those of refined fish oils due to the presence, not only of triacylglycerols as major components, but also of large amount of polar lipids (phospholipids, diacylglycerols, free fatty acids) or other lipid-soluble unsaponifiable components (cholesterol).

Figure 1 shows an example of proton NMR spectrum of a crude lipids extracted using the Bligh and Dyer method [11] from 1-year ripened salted anchovies, caught and transformed in typical area of the Cilento national park (Salerno, Southern Italy). The main resonances, commonly found in all fish oils and lipids are assigned in Table 1. These resonances occur at 0.85 for methyl groups of saturated,*n*-6 and *n*-9 acyl chains, 0.95 ppm for methyl groups of ω-3 components, at 1.65 ppm for the methylene protons in C-3 position, at 2.05 ppm for the allylic protons, at 2.31 for methylenes in C-2, at 2.76 ppm for the doubly allylic protons and at 5.39 ppm for olefinic protons superimposed to glyceryl resonances. In addition to these resonances another signal appearing at 3.37 ppm can be assigned to phosphatidylcholine methyls (Table 1). Some of these signals, therefore, may be used for assessing lipid composition and fatty acid composition. In addition, the careful study of minor resonances detectable in diagnostic spectral zone, the use of high field NMR equipments and 2D experiments, as well as the combination of chromatographic techniques in concentrating minor lipid fractions with proton NMR, allows to obtain, in a short time, very useful informations. The most interesting, with respect to the quality assessment and process control of fish products, are reported in the following paragraphs.

Quantitative Determination of *n*-3 PUFAs

Although fish oils contain many saturated (SFA) and monounsaturated fatty acids (MUFAs), considerable interest is on the identification and quantification of the omega-3 (*n*-3) PUFAs for their intrinsic dietary benefits in human health [12].

Proton NMR spectroscopy offer a rapid and structure-specific way for the global quantitation of n-3 PUFAs in fish lipids, by taking advantage of only two selected proton NMR methyl resonances [4,7–8]. Figure 2 shows a 1D-TOCSY experiment made on a sample of tuna lipids from which the assignment of *n*-3 methyls can be made [5]. When signal at 0.95 ppm was irradiated, a decreasing effect on omega-2 (methylene), omega-3,4 (olefinic) and a residual effect on diallylic (omega-5) can be observed, indicating unequivocally that the methyl at 0.95 ppm corresponds to those of *n*-3 PUFAs. Therefore, the careful

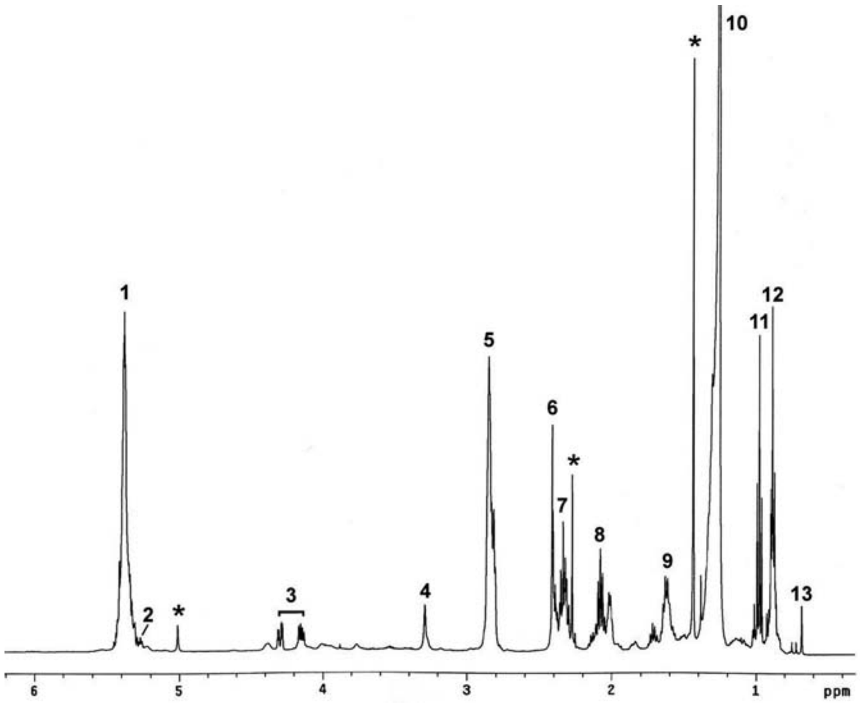

Fig. 1. ^{1}H NMR spectrum of lipids extracted from salted anchovies after 1 year ripening. The spectrum was carried out on a Varian 500 MHz instrument. Peaks are identified as in Table 1. Peaks with asterisks are referred to BHT used as antioxidant during lipid extraction.

Table 1: Assignment of the signals of the ^{1}H NMR spectra of anchovies lipids

Signal	Chemical shift δ (ppm)	Assignment		
		Protons	Functional group	Compound
1	5,30–5,35	**CH**=**CH**	olefinic protons acyl group	unsatured fatty acid
2	5,20–5,26	C**H**OCOR	glyceryl group proton on C2	triglycerides
3	4,10–4,25	$\mathbf{CH_2}$OCOR	glyceryl group proton on C1 and C3	triglycerides
4	3,25	$\mathbf{CH_3}$-N	methyl protons	phosphatidylcholine
5	2,85	CH=CHC$\mathbf{H_2}$CH=CH	bis-allylic protons	polyunsatured fatty acids
6	2,41	$\mathbf{CH_2}$COOR	methylenic protons α position carbonyl group	docosahexanoic acyl group
7	2,32	$\mathbf{CH_2}$COOR	methylenic protons α position carbonyl group	all acyl chains
8	2,02–2,09	$\mathbf{CH_2}$CH=CH	methilenic protons α single double bond	unsatured fatty acid
9	1,62	$\mathbf{CH_2}$CH$_2$COO-	methylenic protons in β position carbonyl group	all acyl chains
10	1,25–1,70	(C$\mathbf{H_2}$)n	methylenic protons of acyl group	all acyl chains
11	0,95	$\mathbf{CH_3}$	methyl protons of acyl groups	ω3 polyunsatured acyl groups
12	0,85	$\mathbf{CH_3}$	methyl protons of acyl groups	all acyl groups except ω3 PUFA
13	0,68–1,02	$\mathbf{CH_3}$	methyls	cholesterol

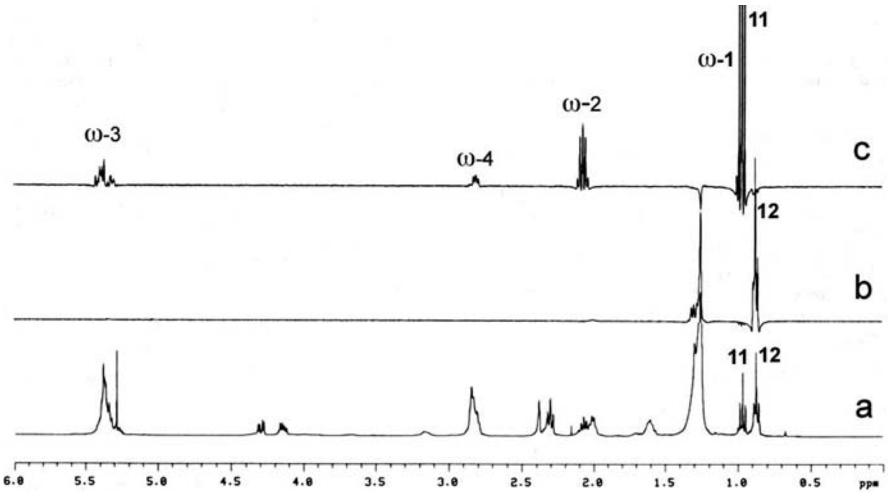

Fig. 2. Identification of ω-3 PUFA methyl resonances by proton nuclear magnetic resonance 400 MHz 1-D TOCSY experiments: (a) full spectrum, (b) selective excitation pulse on methyl triplet at 0.86 ppm, (c) selective excitation pulse on methyl triplet at 0.95 ppm (from ref. 4).

integration of the clearly resolved methyl resonances of n-3 PUFAS (peak n.11 in Figures 1 and 2) and of saturated and *n*-6, *n*-7, *n*-9 MUFAs and PUFAs (peak n.12 in Figures 1 and 2), allows the quantitative measurement of the total *n*-3 components. For this application spectrometers working at reasonably high magnetic fields (10 Tesla or higher) are used.

In a more recent work, the results outlined above have been applied more extensively and proposed as an IUPAC official method for the determination of docosahexanoic acid (DHA) and of n-3 fatty acids in fish oils [8]. In this research several samples of different origin (tuna oil, bonito oil, salmon oil, and sardine oil) were examined in different laboratories and using spectrometers at different magnetic fields to determine the accuracy of the measured peak intensities and, therefore, the quantitation of fish oil composition, in terms of *n*-3 components and DHA. The relative composition (mol%) of the n-3 fatty acids was obtained by simply comparing the relative intensities of the methyl resonances at 0.95 ppm (n-3 fatty acids) with those at 0.8 ppm (all other fatty acids) (Figure 3).

Moreover the DHA relative composition (mol %) was shown to be measured from the assigned C-2 and C-3 proton resonances at 2.38 ppm (peak 6 in Figure 1) well separated from the C-2 methylene protons of the other fatty acids at 2.28 ppm [2]. The DHA weight concentration in mg/g can also be easily measured by comparing its C-2, C-3 methylene resonance intensities with those of known amount of ethyleneglycol dimethyl ether (EGDM) used as internal standard, whose resonances occur at 3.35 ppm (methyls) and at 3.5 ppm (methylenes) [8].

The data obtained in thirteen different NMR laboratories from five different countries (Japan, Norway, Italy, France, and Denmark) were subjected to statistical analyses and demonstrated that both repeatability and reproducibility fall in a quite low range of relative standard deviations and in particular vary between 1.73 and 4.27% for DHA concentrations in mg/g. These values are acceptable for quality control in industrial laboratories and therefore this methodology was proposed as an official method of analysis considering that its major advantage over other possible analytical methods is its operational ease and the non-destructive NMR analysis. The family of n-3 fatty acids is assessed specifically, using proton resonances not affected by molecular weight of fatty acids and lipid classes. In fact, common transterification used for gas chromatographic analysis [13], does not esterify free fatty acids that are not measured by HRGC in highly lipolized oils. In these cases, GC/MS is needed for careful quantification and the use of specific derivatization (treating the sample using diazomethane) or time-consuming esterification methods.

Proton NMR and Lipolysis

Lipid classes and their evolution due to enzymes and thermal processing are a good quality parameter of raw,

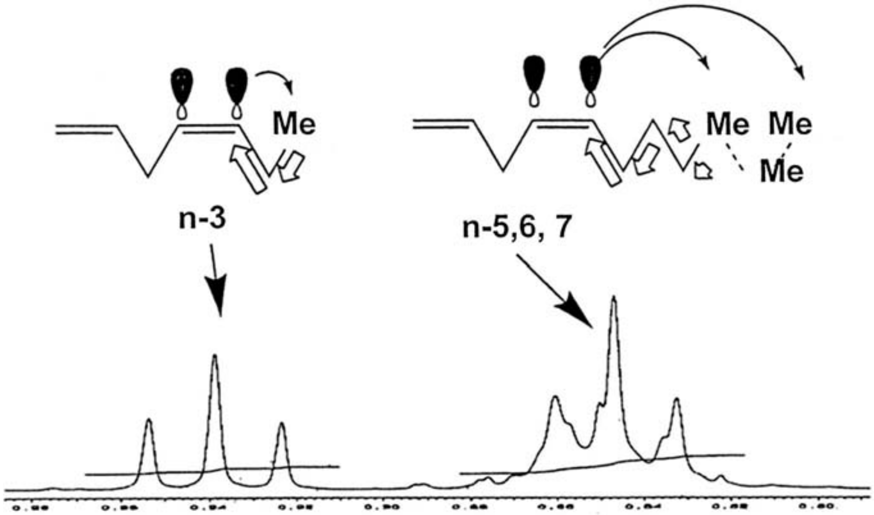

Fig. 3. Principle for quantification of n-3 fatty acids relative composition. (Top) Terminal methyl structures for n-3 fatty acids (left) and other fatty acids (right) where white block arrows and arc arrows show negative inductive effect of sp2 carbons and anisotropic effects of pi-electrons, respectively (Bottom). Methyl region of the ^{1}H-NMR spectrum of a fish oil, where left and right triplets originated from n-3 fatty acids and other fatty acids, respectively (from ref. 8).

processed fish and fish oils. This aspect is better monitored by using carbon-13 NMR [2,6] by observing the carbonyl region (Figure 4). Proton NMR, in fact, does not allow a direct quantitation of carboxyl protons of free fatty acids and in addition methylene protons bound to the carbon C-2 overlap with those of esterified acyl chains. The amount of free fatty acids, important products of fish lipolysis may be indirectly evaluated, only by the ratio between the intensity of diagnostic signals of triacylglycerol moieties (signal n. 4 in Figure 1) and those representative of acyl chain. Diacylglycerol and monoacylglycerol signals are also partially overlapped by phospholipids broad multiplets and not easy quantified.

Oxidation Products

The ^{1}H NMR spectroscopy can be also applied to study the oxidative degradation of fish lipids, by the same approach developed for other oils and lipids [14–15]. This technique is able to detect simultaneously primary and secondary oxidation products in oils and lipids, and to study the effect of industrial processing (salting, thermal treatments, etc.) on lipids [9]. This can be achieved by two analytical strategies. The simplest but of minor applicative interest is the study of the relative intensity changes of the main components, and particularly PUFAs. This approach was followed by Saito *et al.* [10] who demonstrated that the oxidative deterioration of fish oils could be monitoring, estimating the ratio (RO) of olefinic protons (4.90–5.8 ppm) to aliphatic protons (0.5–3.0 ppm). This ratio decreases as the oxidative deterioration proceeds. This procedure is applicable also at low magnetic fields and could be of importance in monitoring industrial processing or in the rapid control of global unsaturation and fatty acid composition.

A second and more interesting application has to be considered, although more difficult and requiring more skilled procedures concerns the study and the identification of new signals in the spectra due to components generated in the oxidation process [14,15].

In an interesting paper Aursand *et al.* [3] have shown, in the proton spectra of oxidised fish lipids, signals at approximately 6.5, 6.0, 5.6, 4.4 and 2.9 ppm originated from the protons of hydroperoxides and conjugated *trans, cis* double bonds formed during oxidation of PUFA , mainly from oxidized *n*-3 double bond [3].

The secondary oxidation lipid products such as aldehydes can also be observed in the proton spectrum [14]. Signals of saturated and unsaturated aldehydic protons between 9.30 and 9.90 ppm have also been detected for unsalted salmon fillet lipids submitted to the oxidation process [9]. In the same paper the lipid oxidation was monitored by measuring changes in relative ratioes of acyl

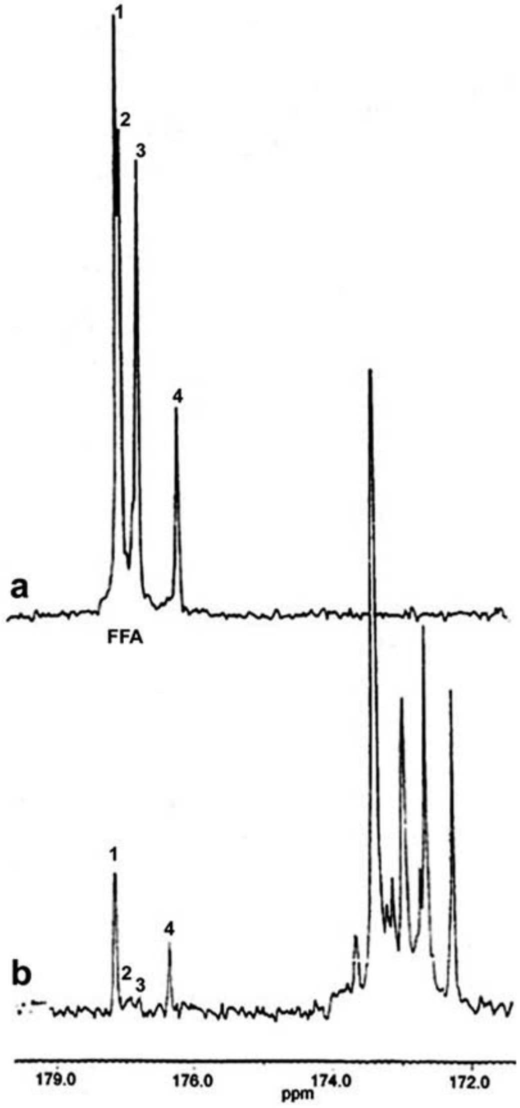

Fig. 4. 13C NMR carbonyl spectral region of a standard mixture of free fatty acids (a) and of a sample of albacore lipids (b). Labelled peaks are assigned as follow: 1 FFA (ST, MUFA); 2 FFA (linoleyl); 3 FFA (EPA); 4 FFA (DHA) (from ref. [5]).

groups belonging to omega-3 and saturated and unsaturated acyl groups.

Application Remarks

The use of NMR methods undoubtedly offers advantages and disadvantages over other analytical techniques. Advantages can be briefly indicated by NMR as being a non-destructive technique and by the ease in determining the relative amount of the main components. Disadvantages are instead due to the limited sensitivity of the NMR method that requires not less than fractions of milligrams for a rapid analysis. In the case of the analysis of fatty acids in fish lipids this point is not a drawback. The determination of minor components is, otherwise, time consuming and difficult although modern equipment developments, such as cryoprobes, can increase the sensitivity range by a factor of 100 thus extending sensitivity to the micromolar range.

Determination of Fatty Acid Composition and Oxidation in Fish Oils by High Resolution Nuclear Magnetic Resonance Spectroscopy

Rosario Zamora, Francisco J. Hidalgo
Instituto de la Grasa, CSIC, Avenida Padre Garcia Tejero 4,41012-Sevilla, Spain

Fatty Acid Analysis of Fish Oils

Fatty acids are key components of fish lipids, and the analysis of them is usually carried out for the characterization of fish oils. Fish oils contain a wide variety of fatty acids (Table 1). Thus, Ackman[1] has reported as many as 50 or 60 components, though only about 14 of these are of importance in terms of weight percent of the total. They are low in saturated fatty acids (mainly myristic and palmitic acids) and high in unsaturated fatty acids, especially those unsaturated acids with long chains containing 20 or 22 carbons or more, and up to six double bonds.

Nowadays, fatty acid analysis is usually carried out by gas chromatography because of the very high resolution together with the high sensitivity and very good reproducibility in quantitative analyses of this chromatographic technique, and the possibility of preparing different derivatives for determining fatty acid structures by GC-MS.[2] However, GC-MS has limitations, being particularly important its inability to distinguish between geometrical isomers and the potential destruction of thermally labile fatty acids.

In recent years, high resolution NMR has emerged as an alternative technique in this field.[3] A NMR spectrum contains a great amount of information that can be obtained in a short time period and the risk of destruction of unstable compounds is minimal. The different signals present in the NMR spectra provide two kinds of information: the chemical shifts and the relative intensities. The former is of qualitative value and it is related to the different atoms present in the analyzed sample, including many structural characteristics of the studied molecules such as the geometry of double bonds or the α and β positions of the triacylglycerols. The latter provides quantitative information of the different signals that can be employed for the quantitative determination of many oil components, including the fatty acids.[4] On the other hand, NMR does not usually distinguish among saturated fatty acids.

In an attempt to critically analyze different studies carried out in recent years, present possibilities and limitations of this technique for the analysis of fish oils and the study of their oxidation are reviewed here.

The ^{1}H NMR Spectra of Fish Oils

Fish oils are composed of more than 95% of triacylglycerols. Therefore, their ^{1}H and ^{13}C NMR are mostly the spectra of the mixtures of their triacylglycerols. Figure 1 shows the ^{1}H NMR spectrum of fish oil from menhaden. This oil contains approximately 25% of $n-3$ (octadecatetraenoic, eicosapentaenoic and docosahexaenoic) fatty acids as triacylglycerols (Table 1). Its spectrum is similar to the spectra of vegetable oils,[5] though some differences are noteworthy. Thus, the signals corresponding to the C2 and C3 methylenes of docosahexaenoic acid (DHA), and the methyl signals of $n-3$ fatty acids are characteristic signals in the spectra of fish oils. In fact, the former signal has been proposed for being employed in the quantitative determination of DHA, and the latter in the determination of $n-3$ fatty acids.[6–9]

The ^{13}C NMR Spectra of Fish Oils

Analogously to the NMR spectra of other edible oils, the ^{13}C NMR spectra of fish oils contain a higher number of signals than their ^{1}H NMR spectra, and it is possible to distinguish among the different fatty acids that are present in the triacylglycerols, and their relative positions. Figure 2 shows the ^{13}C NMR spectrum of menhaden fish oil, which has been assigned according to the chemical shifts previously reported for other oils.[10–12] ^{13}C-NMR signals of fish oils can be grouped into four well-defined spectral regions: carbonyl-carbons ranging from 173.3 to 172.0 ppm; unsaturated carbons ranging from 132.1 to 126.8 ppm; glycerol carbons ranging from 69.1 to

61.6 ppm; and aliphatic carbons ranging from 34.5 to 13.9 ppm. Assignation of aliphatic carbons is given in Figure 3. This figure also includes the spectrum of soybean oil for comparison (panel A).

Because some fatty acid carbons appear differently if they are at the α- or β-positions of the triacylglycerol, it is possible to determine the percentage of the diverse fatty acids at the two positions.[13,14] In addition, the ^{13}C NMR spectrum is very useful to analyze the presence of other components in the oil in addition to the triacylglycerols. These minor components are usually more polar than triacylglycerols and they can be concentrated by chromatographic procedures to obtain good spectra in a short time period.[15] Figure 4 shows the ^{13}C NMR spectrum of the chromatographic fraction obtained from menhaden fish oil. As observed, this spectrum is much richer in signals than the spectrum of the complete oil (Figure 2) and different oil components may be easily observed. Thus, for example, in the glycerol portion of the spectrum, the signals corresponding to mono- and diacyl-glycerols, and cholesterol can be observed in addition to the triacylglycerols. The increased information obtained from these spectra has been employed in defining oil authenticity[16] and quality[17,18] in vegetable oils, and it should also be very useful in the study of fish oils.

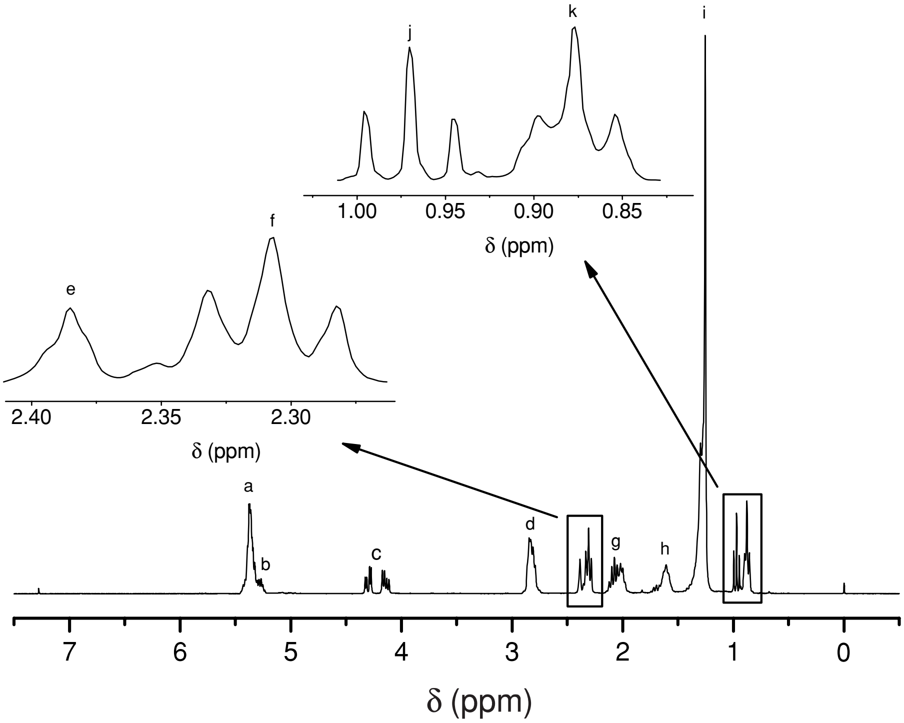

Fig. 1. Three hundred MHz ^{1}H NMR spectrum of menhaden fish oil in $CDCl_3$. Fish Oil Oxidation and its Evaluation by NMR

Lipid oxidation is one of the major causes of food spoilage, and it is particularly important in fish oils because of the high content of polyunsaturated fatty acids with five and six double bonds, which are highly susceptible to atmospheric oxidation. Its evaluation is nowadays carried out by employing different methodologies.[19] Most of these methods are based on the formation of specific compounds or on the modification of others. Because high resolution NMR is able to quantitatively determine many of these components, NMR spectra could be employed to evaluate fish oil oxidation.

Thus, fish oil oxidation produces the decrease of the integrals of olefinic and double allylic protons in fish oils with the progress of oxidation, and the ratios of olefinic protons and double allylic protons to aliphatic protons have been proposed as suitable indexes for comparing the storage conditions of marine products and for estimating the effects of antioxidants on them.[20–22] In addition, good correlations were obtained between ^{1}H NMR and GC data in the study of oxidative degradation of fish materials after cooking.[23]

Nevertheless, the higher amount of information contained in the ^{13}C NMR spectra should produce much more useful spectra. Thus, signals corresponding to free fatty acids can be easily observed when fatty acids are released, and its quantification has been proposed for monitoring free fatty acid release after thermal processing of fish.[24] Other attempts have also been made to study the mechanism of lipid oxidation during thermal stress of fish,[25] but the obtained conclusions were too general, more likely as a consequence of the small changes produced in the obtained spectra.

A better way to observe the changes produced in the spectra is to concentrate chromatographically the polar components produced during oil oxidation[15] Figure 5 shows the ^{13}C NMR spectrum of the chromatographic fraction obtained from a menhaden fish oil heated under air in the dark at 37 °C during 70 h. The formation of

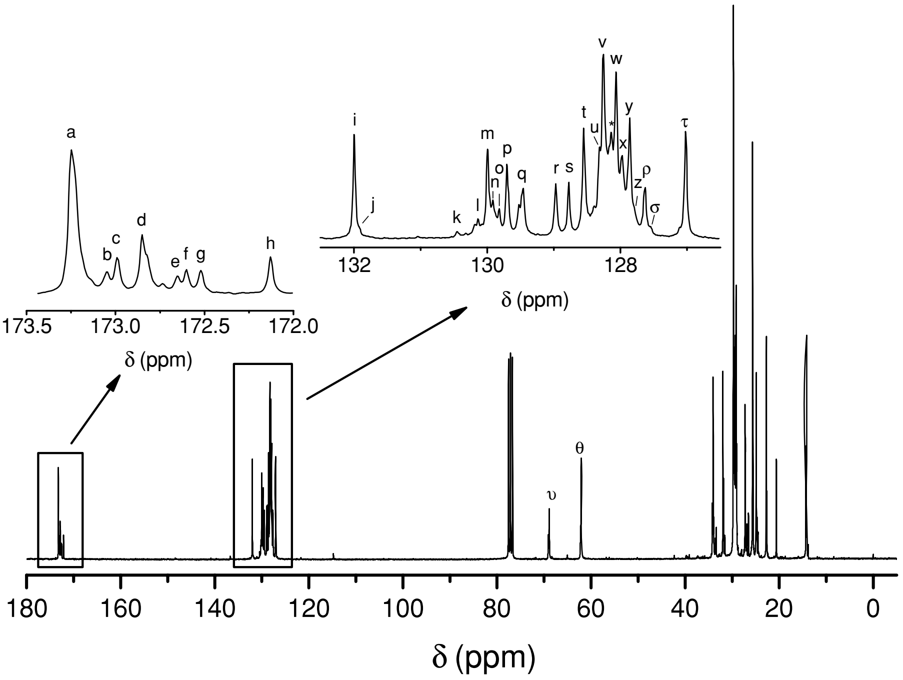

Fig. 2. About 75.5 MHz ^{13}C NMR spectrum of menhaden fish oil in CDCl$_3$. Assignments are abbreviated by fatty acid, carbon number, and position in the glycerol. l(3)- and 2-positions of glycerol are designated by the greek symbols α and β, respectively. The signals ν and θ correspond to the glycerol β and α carbons, respectively. Unassigned peaks are marked with*.

carbonyl derivatives, secondary products of lipid oxidation, is easily observed at $\delta = 210.64$ and 207.12 ppm, though the identity of the produced derivatives has not been determined yet (Zamora and Hidalgo, unpublished results). This soft treatment of the oil did not produce fatty acid release and the most significant changes were observed in the glycerol region. In addition to the increase of the signals corresponding to modified triacylglycerols, the presence of a number of small signals was observed. These corresponded to both primary and secondary products of lipid oxidation. A careful analysis of the changes produced in this region should allow one to follow the different processes occurring as a consequence of lipid oxidation.

Conclusions

High resolution NMR spectroscopy has been shown to be a useful technique for the fatty acid analysis of fish oils. Thus, ^{1}H NMR allows the quantitative determination of DHA very rapidly and with very little sample preparation in comparison with GC. In addition, ^{13}C NMR can be employed to determine the position of the fatty acid chains in the triacylglycerol molecule without any chemical or enzymatic treatment. Furthermore, the chromatographic concentration of the minor oil components allow the direct and simultaneous determination of them by ^{13}C NMR.

Oil oxidation has been less studied by NMR, though a methodology that employs ^{1}H NMR has been developed to follow the oxidation progress. On the other hand, the chromatographic concentration of oil polar components seems to be a necessary step to obtain progress in the study of fish oil oxidation by ^{13}C NMR.

Marine lipids are highly susceptible to lipid oxidation, and analytical methods describing the early stages of lipid oxidation are needed. Free radicals, which are major contributors in the initiation and propagation stages of lipid oxidation, might be detected by different electron spin resonance (ESR) spectroscopy techniques. High resolution (HR) nuclear magnetic resonance (NMR) spectroscopy is less sensitive compared to ESR, but can be applied to identify the different reaction products formed during lipid oxidation. Additionally, HR-NMR can provide detailed information about the chemical composition, which is valuable for predicting the susceptibility to lipid oxidation. This chapter will shed light on some of these techniques applied on marine material.

Electron Spin Resonance Spectroscopy

ESR spectroscopy is a relatively new method for studying lipid oxidation in food systems. It has recently been claimed to be the most direct method for detecting free radicals [1–4]. The method is sensitive and lipid oxidation is detected at its early stages with detection limits of radicals between 10^{-6} and 10^{-10}M at optimal conditions [3–6].

In powder samples, the free radicals are trapped in the food matrix and might be detected directly and nondestructively. Promising results have been reported for radical detection in milk powder [7], dehydrated chicken meat [8], potato flakes [9], and freeze-dried cheese [10]. Saed *et al.* [11] and Howel *et al.* [2], who did their studies on marine powders, reported that ESR could be a tool for studying interactions between proteins and oxidized lipids and found a clear indication of direct free radical transfer from oxidized lipids to amino acids and proteins. Also, direct trapping and identification of radicals were performed, both on systems with and without antioxidant added.

The ESR spectra may provide information for radical assignment by studying the g-value, hyperfine splitting constant and the line shape [3].

At least $2 \cdot 10^{11}$ spins of a specie must be present for seconds to minutes to be detectable directly by ESR [12]. The free radicals active during lipid oxidation in oils and emulsion are labile and are difficult to detect during their shelf life under normal conditions [4]. In such systems, the radicals need to be trapped. Radicals can be trapped by rapid freezing, lyophilisation, and spin trapping [4]. Freezing might disrupt cells and thereby influence the lipid oxidation progress; however, fast freezing will reduce this problem.

Spin trapping is one of the ESR techniques applicable to trap radicals in fluids. Spin trapping agents are chemicals that are mixed in the sample with the purpose of reacting with the free radicals to form detectable and stable spin adducts. There are many spin trapping agents available, but nitrone spin traps are reportedly the most useful when studying lipid oxidation since they react less readily with un-oxidized lipids than nitroso compounds [13]. The most popular spin traps are; N-t-butyl-α-phenylnitrone (PBN), α-(4-Pyrridyl 1-Oxide)-N-tert-butylnitrone (POBN) and 5,5-dimethyl-1-pyrroline-N-oxide (DMPO) [14]. Characteristics of the different spin traps are reviewed by Janzen and Haire [15]and the specificity of spin traps to different free radicals are reported in tables of spin adduct ESR parameters [14]. During lipid oxidation both alkyl and oxygen centered radicals are formed, which is one of the aspects to allow for when choosing the spin trap and the experimental conditions. PBN adducts with oxygen centered radicals have too short a half lifetime to be detected by ESR, resulting in trapping of mainly carbon centered radicals when using PBN [16]. DMPO however, can trap both carbon centered radicals and hydroxyl radicals [16], but this is a hydrophilic spin trapping agent which might restrict its applications in oil systems. A lipophilic derivative of 5-(diethoxy-phosphoryl)-5-methyl-1-pyrrolineN-oxide (DEPMPO) has been recently developed for successful trapping of carbon- and oxygen centered radicals [16]. There is on-going research with the aim of developing new spin traps, but according to Stolze *et al.* [17], no optimal spin trap for detection of alkoxyl radicals has yet been found.

Graham A. Webb (ed.), Modern Magnetic Resonance, 933–940.
© 2008 *Springer.*

The spin trapping technique has recently been applied to bulk oils and food model emulsions [6,18–22]. A fish oil-enriched mayonnaise system was developed [6,18–21] to study the oxidative stability (tendency of radical formation) and efficiency of antioxidants [18,6]. Additionally, quantification of free radicals was successfully performed in this system [6]. In bulk oils a correlation was found between ESR and accelerated oxidative stability methods (Rancimat) during evaluation of oxidative stability [23] in vegetable oils with and without volatile antioxidants. ESR was also found consistent with conventional methods during oxidation of cod liver oil and salmon oil [22].

ESR has provided much to the science of antioxidant effect [3,23–25] and elucidation of the reaction mechanisms involved [26]. Such work is important, especially for marine lipids, since they are regarded as health promoting products and need to be stabilised against destructive lipid oxidation. However, few reported studies are dealing with free radical detection of the complex marine lipids.

Investigation of Free Radicals in Marine Lipids

Several preliminary studies have been recently conducted in our research group to explore the applications of ESR as a tool for evaluating lipid oxidation in different marine material (raw material, bulk products, and fillets). Parts of this work are briefly presented here, focusing on opportunities and limitations concerning the method.

Study of Lipid Oxidation in Freeze Stored Herring

Among other analytical techniques, ESR was used to study lipid oxidation in herring mince during frozen storage. Herring mince was stored with and without added α-tocopherol at −20 °C for up to 6.5 months. A control sample of the same mince was kept under vacuum at −80 °C until analysis. Three different ESR techniques were tested; (1) direct detection in the mince, (2) spin trapping in a MES (2-[N-morpholino] ethanesulphonic acid) buffer emulsion (POBN) and (3) direct detection in the vacuum freeze dried samples.

ESR measurements were performed at room temperature using an X-band (9.45-GHz) ECS ESR 106 spectrometer (Bruker, Rheinstetten, Germany). No detectable signals were obtained when directly recording spectra from the mince placed in a flat EPR cell. A method based on an assay developed for measuring lipid oxidation in meat products [27], was adopted for the spin trapping experiment in herring. The mince (2.4 g) was homogenised with a MES buffer (24 ml) containing POBN (40 mM). Samples were placed in a water bath kept at 35 °C and ESR recordings of the filtrate were performed at certain time intervals. The spectrum and the increased intensity of POBN spin adducts are presented in Figure 1 showing signal increase a short time after preparation of the emulsion. Higher signals were found in the oxidised sample. Spectra from direct detection of the freeze-dried

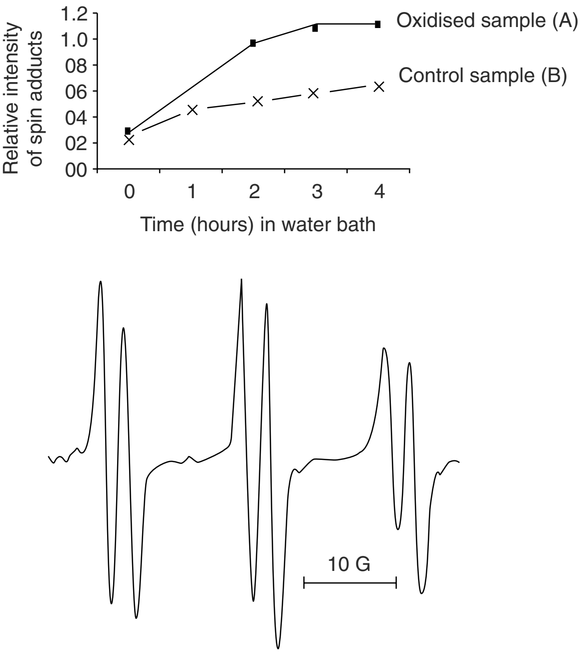

Fig. 1. Intensity of spin adducts (POBN) in herring mince in the control sample (B) (mince, vacuum packed and kept at −80 °C until analysis) and (A) mince freeze stored for 6.5 months at −20 °C before analysis. The methods are adopted from an assay reported by Carlsen *et al*. [27]. An ESR spectrum from this series is also presented. Unpublished data.

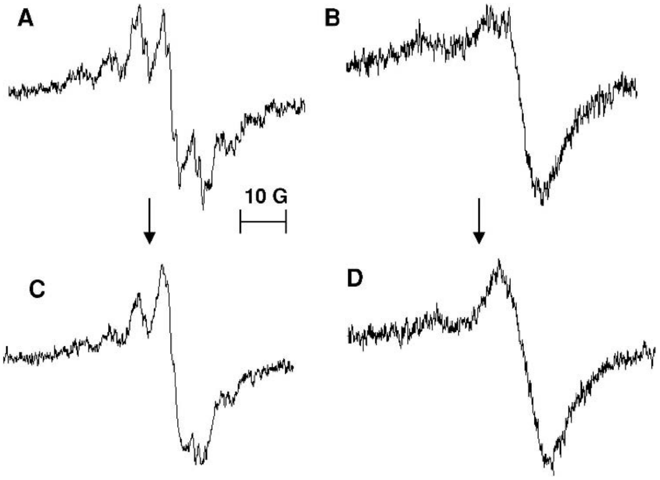

Fig. 2. ESR spectra of freeze dried samples of herring mince. Samples A and B are control samples (mince stored at −80 °C until analysis). Samples C and D are the same samples freeze stored at −20 °C for 6.5 months before analysis. Samples A and C are added 200 ppm α-tocopherol as antioxidant. Unpublished data.

mince are shown in Figure 2 and it is quite clear that the method is capable of separating samples with and without α-tocopherol based on the ESR spectrum. The signal intensity in the stored/oxidized samples was higher than in the control samples. Our unpublished data has shown that the free radical signals in a series of dried marine powders are reduced during further storage and that the reduction is faster at higher temperatures. The direct detection of radicals in marine powders might be affected by transition metals like iron and copper, which from time to time are found in detectable amounts in these products (natural or by contamination by processing equipment). The spectra will, in that case, be disturbed (see Figure 3) but information about the metal ions can in that case be gained. The importance of using optimal microwave power is illustrated in Figure 4.

Spin Trapping of Cod Liver Oil

In order to find the optimal spin trap and the stability of spin adducts in a fish oil system the following three common spin traps were used in fresh cod liver oil: 2N-t-butyl-α-phenylnitrone (PBN), α-(4-Pyrridyl 1-Oxide)-N-tert-butylnitrone (POBN) and 5,5-dimethyl-1-pyrroline-N-oxide (DMPO). The spin traps were added at two

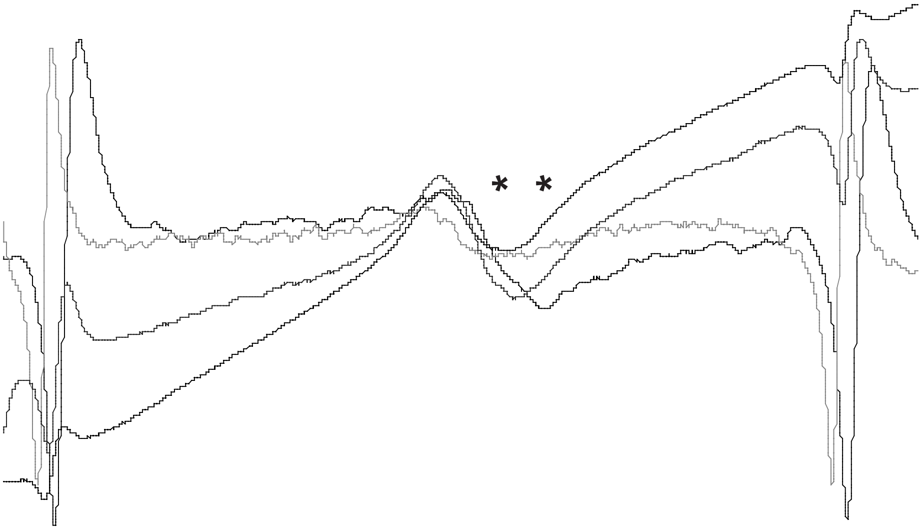

Fig. 3. ESR spectra of fish protein hydrolysates dried by different techniques. The two spectra of spray dried samples (*) has changed the shape which indicates a contamination by transition metals (∼g = 2.00).

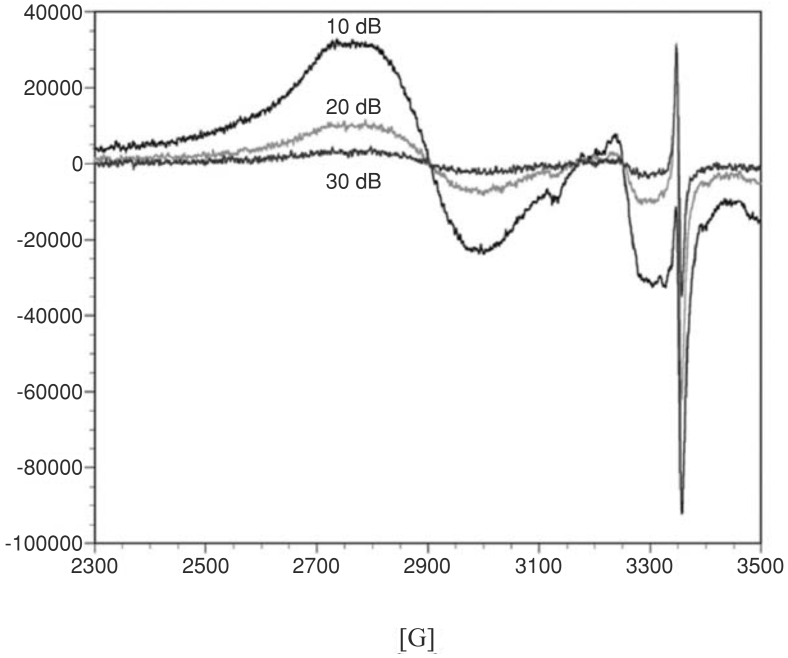

Fig. 4. ESR Spectra of salmon powders using three different microwave powers. Temp 180 K, mod amp 1.0 G, Gain 210^5.

concentrations (1 and 3 mg/g oil) and ESR spectra were recorded at specific intervals after storage in a water bath set at 40 °C. The amplitude of the ESR signal is expressed as the relative intensity of free radicals during storage and is presented in Figure 5. Spin adducts from PBN and POBN (3 mg/g) reach a maximum between 50 and 120 h at 40 °C, while the maxima reach a lower value in the samples with 1 mg/g. The amounts of spin adducts are relative similar between PBN and POBN, while the signals are much more complex and lower for the spin adducts with DMPO. This might be due to the solubility properties.

In another study, cod liver oil with different levels of lipid oxidation (0, 1, 2, 3, 4 weeks at 40 °C) with added PBN as spin trap was investigated by the same procedure as above (Table 1). The aim of this study was to see whether the different oxidation levels could be separated (valuable as a stability test) and to study the stability of spin adducts. However, no systematic differences in radical formation were found among the different samples. The stability of the spin adduct varied among the samples, but during the first 24 h at 40 °C the intensity of spin adducts was drastically reduced in all samples. Because of the high unsaturation of marine lipids, double bounds will be present for further reactions also after major oxidation. The trapping will therefore mainly be limited by the concentration of spin trap added.

However, the spin trapping might be affected by anti- and pro-oxidants in the system which is illustrated in Figure 6. This experiment was performed by the same procedure as for the PBN in the experiment presented above, except for addition of, respectively, iron (FeII-powder) and α-tocopherol in the spin trap. The sample containing iron exhibited increased amounts of spin adducts compared to the control, while the sample with added α-tocopherol had a lower production of spin adducts.

From our experience in spin trapping with PBN in fish lipid systems, large differences in the persistence of spin adducts have been found [22]. Using similar conditions (1 mg PBN /g oil in pure lipid stored at 40 °C in the ESR tube) the persistence of spin adducts ranged from minutes in ethyl docosahecaenoate up to 200 h in certain, gently extracted, cod liver oils. This might depend on the degree of lipid oxidation, refining, and certain antioxidants. This indicates that these systems are complex and endogenous compounds might be affecting the spin trapping and lipid oxidation. The spin trap itself will also affect the lipid oxidation by acting as an antioxidant (unpublished data, Falch) in fish oil systems.

NMR

Among the NMR techniques, ^{1}H NMR has been most widely used for studying lipid oxidation. Previous work has reported a decrease of the ratios between olefinic

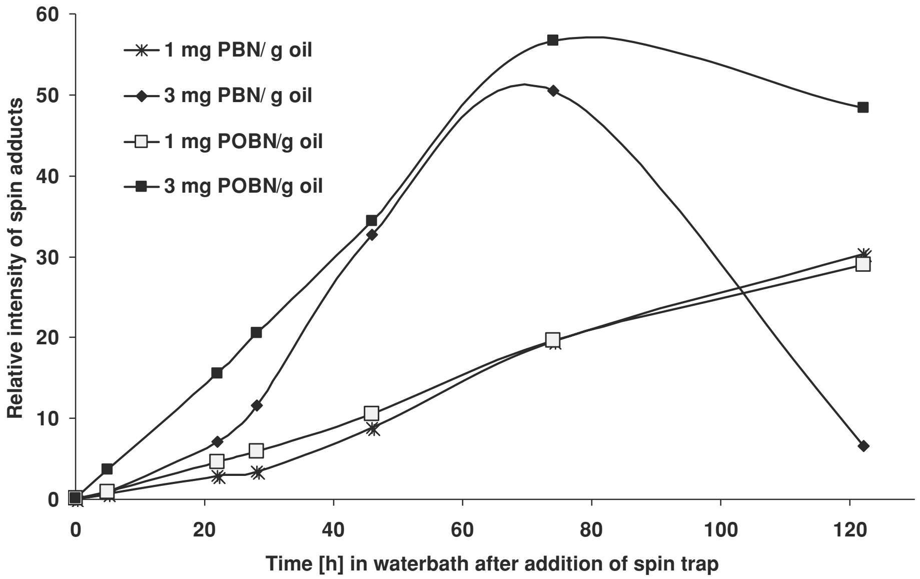

Fig. 5. Spin adducts from POBN and PBN in cod liver oil at different concentrations (1 and 3 mg/g oil) during storage in the tube at 40 °C. The signals are measured by the amplitude of the middle peak. Instrumental settings: sww 5mT, swT 4 min, Mod width 0.2 mT, cf 335.6mT, timec 1 s (Jeol X-band). Unpublished data.

(∂ 5.1–5.6 ppm) to aliphatic protons (∂ 0.6–2.5 ppm) and aliphatic to diallylmethylene protons (∂ 2.6–3.0 ppm) during lipid oxidation. These results were obtained from experiments on vegetable- [28–30] and marine lipids [31–35]. Additionally, a correlation has been found between this ratio and the peroxide value [28,30,32,35]. However, relatively high levels of lipid oxidation are reported before any detectable changes in the NMR spectra occured.

^{1}H NMR has been reported to be valuable for evaluating the changes in lipids due to lipid oxidation in vegetable oils [30,36], including identification of hydroperoxides, conjugated diene hydroperoxides, saturated and unsaturated aldehydes, acids and ketones in the spectra. In a recent study [37], we have investigated lipid oxidation in ethyl docosahexaeoate using ^{1}H NMR and detected many of the same reaction products generated during lipid oxidation including cyclic compounds. Spectra of oxidized fish oils show clear development of peaks in the downfield region of the spectra (8–10.5 ppm) where no other signals are localized in lipid extracts (unpublished data). Chemical shift values (^{1}H) associated with the lipid oxidation are presented in Table 2. One of the main benefits of using NMR is that the spectra can provide information on a broad range of compounds, including not only the reaction products formed during lipid oxidation, but also the chemical composition in general and how it is affected by these reactions (e.g. unsaturated fatty acids). A good example of this is the reported differences in oxidizeability between different lipid components like unsaturation of fatty acids, position of double bonds, positional distribution of fatty acids within the acylglycerols [38] and amount of free fatty acids (hydrolysed phospholipids and triacylglyceroles). This is information that is possible to gain from ^{13}C and ^{1}H NMR spectra [39,40–43]. NMR can provide information on both lipid composition and how the composition changes due to lipid oxidation and lipolysis. It is necessary that the compounds are at detectable levels, which is one of the limitations at this stage. Detection levels in^{1}H NMR are reported to be <0.01 mM [37], however, optimization of the instrumental systems (e.g. 800 MHz magnet equipped with a cryoprobe) will improve the detection limits.

Multivariate data analysis is helpful and, in some cases, necessary for differentiating samples due to the differences in lipid oxidation, especially cluster analysis and generic algorithms, since they, respectively, separate samples based on their dis-similarity and extract what chemical shift areas are causing these differences [36]. With the help of cluster analysis, we have also been able to separate herring mince stored at different lengths of freeze storing based on the differences in^{1}H spectra which were difficult to read by studying the individual spectra.

HR-magic angle spinning (MAS) analysis was performed on the same herring mince. Development of peaks

Table 1: Relative intensity (ratio between the signal amplitude and the reference sample (Manganese)) of spin adducts in cod liver oil added PBN as spin trap. The oil were pre-oxidised at 40 °C in 0, 1, 2, 3, and 4 weeks before addition of spin trap. Spectra were recorded after 0, 1, 2, 3, 4, 5, and 24, 48, 72, and 96 h of further oxidation at 40 °C. Instrumental settings: sww 5mT, swT 2 min, Mod width 0.2 mT, cf 335.6 mT, timec 1s (Jeol X-band). Unpublished data

in the downfield regions (8–10.5 ppm) was found in the ^{1}H spectra of the most oxidized samples. In tissue samples also signals from phosphometabolites (degradation of ATP) [44] are found in this region of the spectra, which complicates the assessment.

Concluding Remarks

Different ESR techniques provide valuable information regarding the early stages of lipid oxidation in marine material. Some precautions need to be taken since this is a complex chemical system and endogenous substances may affect the analysis. By supplementing this method by NMR, information on the consequences of lipid oxidation could be obtained, but relative high-detection limits with todays equipment is a limiting factor. Investigation and assignment of spin adducts and their shelf life might be obtained by combining ESR and NMR (on-going work). ^{13}C NMR could be used to study the specific spin adducts and how they further react when we see the reduction of signals.

Introduction

The nutritional benefits of fish and fish oils have resulted in an increasing interest in seafoods and derived products generally focused on the level of omega-3 (*n*-3) fatty acids (FAs). In particular 20:5 *n*-3 (EPA) and 22:6 *n*-3 (DHA) are believed to play a natural, preventive role in cardiovascular diseases, and alleviation of other health problems [1,2]. Aquaculture opens up interesting possibilities for exerting a control over factors affecting the nutritional and sensory attributes of fish as food such as the quantitative and qualitative content of fat in the edible tissues. About 20% of the muscle lipids of farmed Atlantic salmon are *n*-3 FAs, with some variation due to the FA composition of the fish feed. The content of EPA and DHA in muscle of farmed Atlantic salmon has been found to be approximately 0.6 and 0.8 g/100 g of fillet, respectively [3].

Traditionally, gas chromatography (GC) has been used to obtain the FAs profile of lipids. This technique requires that the sample is pretreated, extraction and methylation of the lipids have to be included as part of the analysis [3]. Recently it has been demonstrated that high-resolution nuclear magnetic resonance (NMR) spectroscopy can be used to provide insight into the nature of lipid mixtures and offers the opportunity to study hetereogeneous lipid mixtures, oils and fat deposits without being destructive [4–7]. NMR measurements can be performed on intact muscle and allows the identification and quantification of muscle metabolites [4,7,8] addition to lipid fluidity studies in fish muscle stored at low temperatures [9]. In preliminary studies ^{13}C NMR has been used to obtain the *n*-3 FA content of intact fish muscle [7,10]. The ^{13}C NMR experiment on intact muscle is very time consuming and it would be an advantage to detect on ^{1}H instead of ^{13}C due to the facts that ^{1}H NMR has the highest NMR sensitivity of any stable nucleus, and it has nearly 100% natural abundance. In our preliminary research it has been shown that high-resolution ^{1}H NMR is a unique and rapid technique to quantify the total *n*-3 acid content of the lipid extracted from muscle of Atlantic salmon [5,7]. A traditional ^{1}H spectrum of intact muscle will only result in broad signals containing fat/water proton resonances and individual FAs or groups of lipids are not observed. However, recent research indicates that magic angle spinning (MAS) NMR spectroscopy offers the opportunity to study intact tissue non-destructively to quantify components of the tissues. Ni and Eads [11,12] have studied fruit tissue and they have shown that low-speed MAS simultaneously relieves susceptibility broadening, improves resolution, produces accurate chemical shifts, and increases signal-to-noise ratio.

In the present study, we have obtained ^{1}H MAS NMR spectra of intact salmon muscle and quantified the total *n*-3 acid content from the spectra. The data from the MAS NMR analyses were compared to those obtained by estimating the fat content in extracts from equivalent muscle samples by ^{1}H NMR and by GC. The results from MAS NMR and from ^{1}H NMR were usually in good agreement, while the content of *n*-3 estimated by GC was in general higher than if estimated by the NMR techniques.

Experimental Procedures

Material and Sample Preparation

The white muscle of five commercially farmed Atlantic salmon (*Salmo salar*), of about 3–4 kg of weight each, were used in the present study. Slices of white muscle were carefully cut from the area between the head and the dorsal fin and each slice was divided into two parts (about 5 mm^3) one of the slices was carefully introduced into a MAS NMR rotor (5 mm). The other slice was used to extract muscle lipids according to Bligh and Dyer [13]. Part of this lipid extract, containing 50 mg of lipids, was dissolved in 0.5 ml of $CDCl_3$, introduced into a 5 mm NMR tube and analyzed by ^{1}H NMR. The rest of the lipid

Graham A. Webb (ed.), Modern Magnetic Resonance, 941–945.
© 2008 *Springer.*

extracts were stored at −80 °C prior to methylation and GC analysis.

Gas Chromatography

FA methyl esters were prepared according to Metcalfe *et al.* [14]. The FA methyl esters were determined quantitatively on a capillary gas chromatograph (Carlo Erba HRGC 5160 series equipped with a SP-2330 glass capillary column, on-column injection, and flame ionization detector) fitted with a Shimadzu-Chromatopac C-R3A computation integrator. Identification and quantification were carried out using FA standards.

NMR Spectroscopy Experiments

The conventional ^{1}H NMR spectrum of lipid extract of muscle was obtained on a Bruker AM 500 MHz spectrometer at ambient temperature. The FID was acquired with a pulse delay of 6 s, using a sweep width of 8 kHz and 16 K data points. Thirty-two scans were collected using a 45° excitation pulse. The ^{1}H MAS experiments were acquired on a 4.7 T NMR instrument (Bruker, Karlsruhe, Germany) operating at 200.13 MHz for protons. For MAS experiments the rotor axis makes an angle of 54.44° with the static field (MAS). The MAS spinning rate was 1500 Hz. The spectra were acquired with a single-pulse sequence with a delay time of 5.4 s, 16 scans, and 7.4 µs excitation pulse length. A sweep width of 8192 Hz and 16 K data points were used. The water peak was suppressed using a presaturation pulse.

The peak areas of the NMR MAS spectra were measured using a curve fitting program (PeakFit Jandel Scientific, USA), and the integrals of the peaks in the ^{1}H NMR spectra of lipid extracts were obtained by a program developed at the Norwegian University of Science and Technology (NTNU), Trondheim.

Results and Discussion

Previous research has shown that ^{13}C NMR determination of the total concentration of lipids and groups of FAs within muscle of Atlantic salmon is possible due to the lipid-like nature of the tissue lipids, with high content of polyunsaturated FAs [7]. Generally, muscle lipids of Atlantic salmon are mainly composed of triacylglycerols which are incorporated into connective tissue of

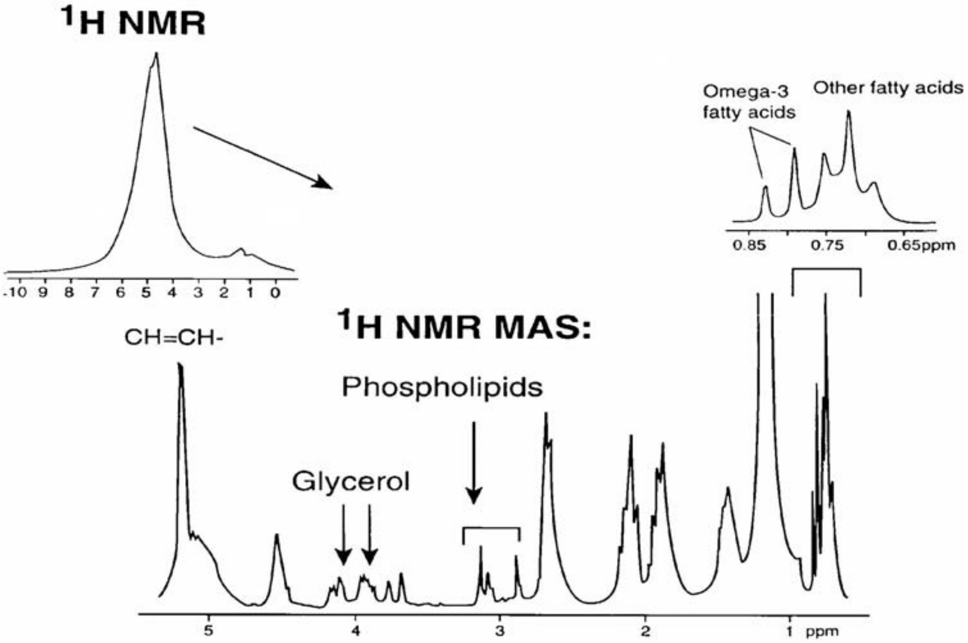

Fig. 1. Effect of magic angle spinning (MAS) on the^{1}H NMR spectra of intact muscle from Atlantic salmon. Upper left spectrum: non-MAS spectrum obtained in conventional high-resolution probe. Lower center is a MAS spectrum. The upper right inlet is an expansion of the lower MAS spectrum between 0.6 and 0.9 ppm, indicating the region of the *n*-3 FAs. Sample preparation and NMR parameters are described in the text.

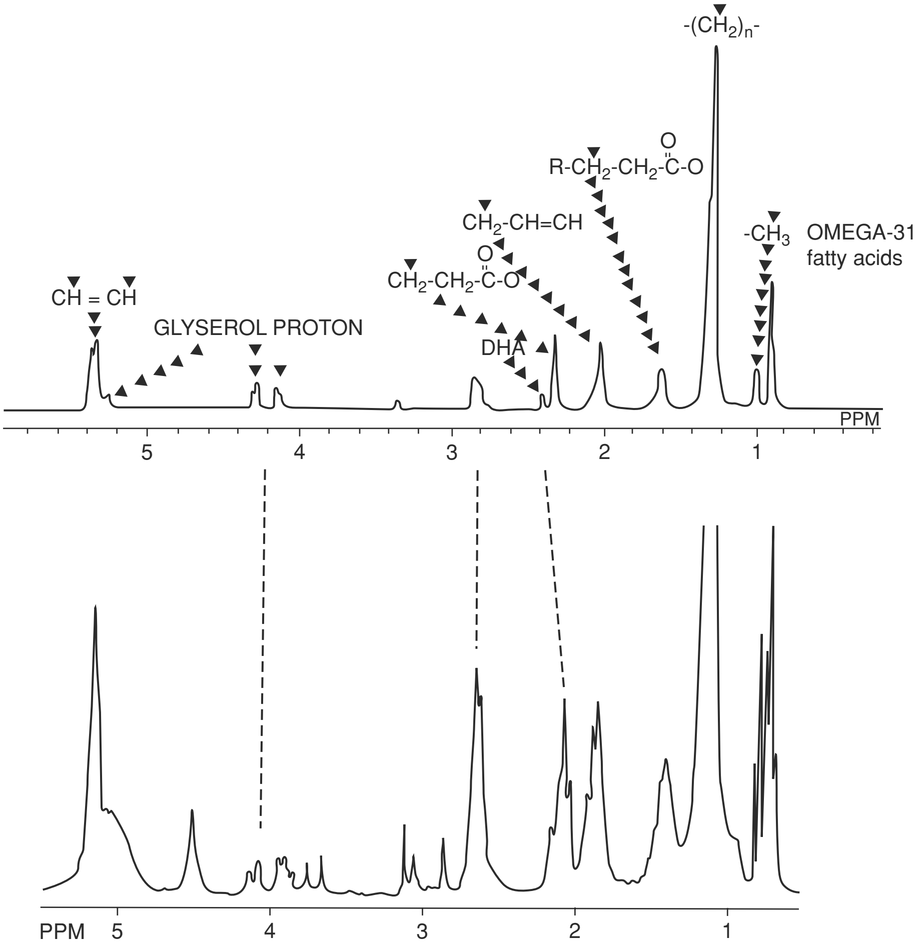

Fig. 2. Comparison of ^1H NMR spectra of lipid extract of muscle of Atlantic salmon (upper spectrum) and that obtained by ^1H MAS NMR of intact muscle (lower spectrum). Sample preparation and NMR parameters are described in the text.

muscle surrounding bundles, single cells, and inside muscle cells. However, because the lipids are not distributed homogeneously within the muscle tissue there is a considerable line broadening in NMR spectra from intact muscle, resulting in less resolution and sensitivity than in the NMR spectra of lipid extracts The line broadening originates from the heterogeneous nature of the muscle and, ultimately, from induced dipolar fields produced by differences of bulk magnetic susceptibility depending on the microenvironment of the lipids, the microenvironment inside the adipocytes is different from that inside myocytes which in turn is also different from that in the extracellular matrix [15,16]. Thus, examination of intact muscle by conventional ^1H NMR, gave broad proton resonances, and in addition, the strong water proton resonance made water peak suppression necessary. To minimize potential alterations in the sample during the NMR MAS measurements, one should use the lowest possible spinning rates. Accordingly, we tested the effect of spinning rates varying from 500 to 3000 Hz, and found that optimal resolution of the ^1H spectrum of intact salmon muscle was obtained by using a spinning rate of 1500 Hz and water peak suppression.

Figure 1 compares two spectra from intact muscle: the upper left spectrum was obtained in a conventional high-resolution probe (sample axis parallel to magnetic field, non-spinning) and the lower one was obtained with MAS probe. The great improvement achieved by the latter made the resolution of the NMR MAS comparable to that of the ^1H spectrum of the lipids extracted from the contiguous muscle tissue (Figure 2). The interpretation of these spectra is based on previous published works [7,17]. Resonances of FAs in triacylglycerides and phospholipids as well as those from other muscle metabolites, were easily identified in the MAS spectrum. The unique methyl proton (–CH_3) of the n-3 FAs gives rise to partly resolved signals in the MAS spectra allowing quantification of the total n-3 acid content of intact muscle. Due to some overlap, a curve fitting program was used to measure the areas under the methyl peaks which allow us to estimate the relative percent of n-3 FAs in intact salmon muscle.

From the lipid extract spectrum it was possible to calculate the content of the highly polyunsaturated FA 22:6 n-3, as well as the total amount of n-3 FAs, by integration of the unique signals with chemical shifts of $\delta = 2.38$ ppm and $\delta = 0.95$–0.98 ppm (a triplet), respectively [7,19], as shown in Table 1. However, the MAS spectra did not permit to resolve the signals of the C2/C3 protons (–COO–CH_2–CH_2–CH=, $\delta = 2.38$ ppm) of 22:6 n-3 from the signals of the C2 protons (–COO–CH_2–R, $\delta = 2.28$ ppm) from other FAs present in muscle tissue. Consequently, the resolution of the spectrum obtained by MAS was not sufficient to permit the quantification of 22:6 n-3 FAs in intact muscle.

The values of n-3 FA content estimated by MAS NMR and by ^{1}H NMR of the corresponding lipid extracts were in good agreement (Table 2). As expected, baseline correction had considerable influence on the estimated peak area values. Additionally, the resolution of the MAS spectrum was affected by the position of the sample into the small MAS tube.

For comparison purposes, the content of FAs of the lipid extracts was also estimated by GC. The correlation between the GC derived data (weight %) and the ^{1}H NMR data (mol %) is illustrated in Figure 3. Relatively good correlation was observed ($r^2 = 0.81$, $p < 0.01$). However, GC gave generally higher n-3 acid values than NMR. The same trend was observed in a study done by Sacchi *et al* [19]on albacore tuna. Some of the differences can be explained by the fact that in the NMR measurement are done on the hetereogeneous lipid mixture containing phospholipids, sterols, etc. while the additional procedures to which the lipid extract is submitted prior to GC may results in changes in the relative composition of the FAs. This aspect is under further investigation.

In summary, this study shows that ^{1}H MAS NMR spectroscopy is an exceptional technique for the determination of the total content of n-3 FAs in intact salmon muscle. More research is needed to optimize the MAS NMR and the conventional NMR experiments together with intercalibration work between the NMR and GC techniques.

Table 1: Omega-3 fatty acid, DHA (C22:6 n-3) and cholesterol content (mol %) of white muscle of farmed Atlantic salmon examined by high-resolution ^{1}H NMR spectroscopy

Sample	Omega-3 fatty acids	DHA (C22:6 ω-3)	Cholesterol
Salmon 1A	18.4	12.1	0.7
Salmon 2B 1	22.7	14.6*	1.8

Salmon 4D 1	18.9	12.3	1.0
Salmon 4D 2	18.5	12.5	0.9
Salmon 5E 1	21.6	15.7 (3.2)	1.5
Salmon 5E 2	23.0	16.7	1.8

*Incorrect baseline.

Table 2: Omega-3 fatty acid content (mol %) of white muscle of farmed Atlantic salmon measured on intact muscle and the lipid extracted from the corresponding muscle examined by ^{1}H MAS NMR (200 MHz) and high-resolution ^{1}H NMR (500 MHz), respectively

Sample	1H MAS NMR intact muscle	1H NMR lipid extract [13]
Salmon A	19.7	18.4
Salmon 2B 2	17.3	22.7
Salmon 3C 1	23.9	19.5
Salmon 3C 2	16.4	19.7
Salmon 4D 1	15.9	18.9
Salmon 4D 2	19.9	18.5
Salmon 5E 1	21.3	21.6
Salmon 5E 2	22.4	23.0

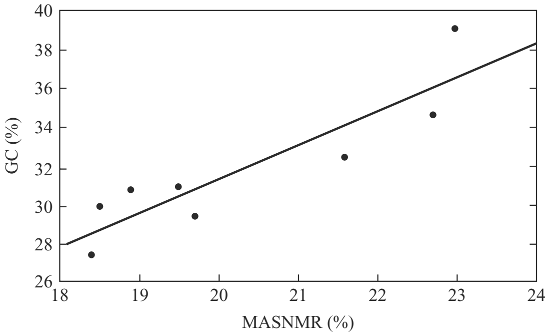

Fig. 3. Correlation between gas chromatography derived data (wt %) and the ^{1}H NMR data (mol %): $Y = -3.7 + 1.75X(r^2 = 0.81;\ p < 0.01)$. Sample preparation, GC and NMR parameters are described in the text.

In general, the NMR is a rapid, non-invasive, and non-destructive method, with an experimental time of about 1–2 min. This opens up possibilities to examine the *n*-3 FAs in fish and fish products without any chemical pre-treatment of the products making NMR, a valuable tool in the nutritional evaluation and general quality control of fresh and processed fish products.

HR MAS NMR Spectroscopy of Marine Microalgae, Part 1: Classification and Metabolite Composition from HR MAS ^{1}H NMR Spectra and Multivariate Analysis

Matilde Skogen Chauton[1] and Trond Røvik Størseth[2]

[1] *Trondhjem Biological Station, Department of Biology, Norwegian University of Science and Technology, 7491 Trondheim, Norway; and*
[2] *Sintef Fisheries and Aquaculture, 7465 Trondheim, Norway*

Introduction

Marine microalgae, or phytoplankton, have been termed the "grass of the sea" since they are the primary producers that form the basis of marine food chains. They are found naturally throughout all aquatic environments, and can be cultured for feed production or for experimental purposes. Some microalgae are toxic, such as those involved in shellfish poisoning. Others have long spines on the cell that can cause mechanical damage to fish gills, and some species form gelatinous aggregations which can hinder gas exchange in fish gills [1]. The nutritional value of microalgae depends primarily on the amount and composition of amino acids and fatty acids, and diatoms contain many of the desired compounds [2]. Since microalgae are so important both in terms of beneficial primary production but also as the cause of fish or human death by poisoning, we have developed several technological solutions to survey the distribution and amounts of microalgae in the oceans. On a larger scale, satellite measurements of chlorophyll *a* (Chl *a*) and buoys equipped with spectroradiometers that measure light extinction are used to estimate the standing stocks of microalgae in the oceans and coastal areas. For more detailed information, laboratory studies often involve species identification and cell counts with light microscope, spectrophotometric measurements of Chl *a* and *in vivo* light absorption, or pigment chromatography for identification and biomass estimation based on group specific pigment composition [1,3]. There are, however, some drawbacks to these well-established methods, both related to the time spent on the analysis run and the use of organic solvents. Each method aims at specific cellular structures or metabolites and the different methods are therefore often combined to increase the information output. This means that even more time is spent on the analytical work, while with the HR MAS NMR spectroscopic methods it is possible to analyze complex samples such as tissue and cells in relatively short time, and the information output from each analysis includes data on many different metabolites.

In principle, NMR analysis of whole microalgae cells should give a detailed description of the chemical profile, or the metabolome [4]. Application of special pulse techniques such as water presaturation or Carr–Purcell–Meiboom–Gill (CPMG) further enhances the results by eliminating undesired signals from residual water in the sample or from lipids in cell membranes [5–7]. HR MAS NMR directly on whole cells can also be used for studies of cellular distribution of metabolites, since small metabolites in liquid compartments have different NMR properties than larger molecules in rigid environments.

HR MAS NMR-studies on human body fluids are quite numerous [8–10], and application of NMR in studies of higher plants is reviewed by Ratcliffe *et al.* [11]. Some examples of HR MAS studies on whole cells or tissue from lower organisms are such as on the yeast *Pichia anomala* [12] or macroalgae [13]. HR MAS studies of microalgae whole cells are scarce [14–18]. We present the results of HR MAS ^{1}H NMR analyses on microalgal whole-cell samples, where focus is on taxonomic discrimination (classification) and metabolite profiling. In the Part 2 of this work, we focus on ^{13}C and HR MAS ^{13}C NMR analysis of fatty acid composition and polysaccharide structure in microalgae.

Results and Discussion

Chemical composition in hydro- and lipophilic extracts of the diatom *Thalassiosira pseudonana* Hasle and Heimdal was studied with proton NMR spectroscopy, and the results were compared to a HR MAS ^{1}H NMR spectrum of whole cells [16]. Signals from important metabolites such as polyunsaturated fatty acids (PUFAs), eicosapentaenoic acids (EPAs), and docosahexaenoic acids (DHAs) were seen in a ^{1}H NMR spectrum of lipophilic extract, and possibly also signals from carotenoids. In the cells, the FAs are important constituents of cell membranes, while carotenoids and other pigments are used in light harvesting and conversion of light energy to chemical energy such as ATP. In a spectrum of hydrophilic extract, we assigned

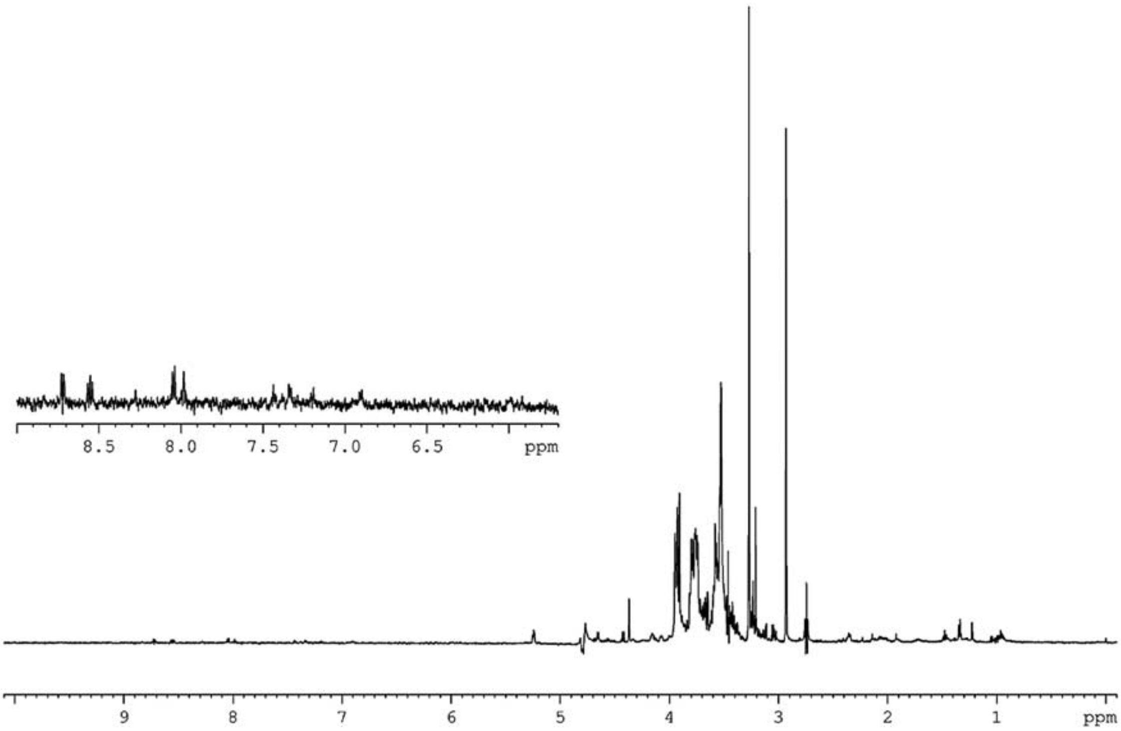

Fig. 1. HR MAS ^{1}H NMR spectroscopy analysis of whole cells of *Thalassiosira pseudonana*. Reference TSP 0 ppm. Inserted spectrum: expansion of low-field region 9–5.7 ppm.

signals to amino acids such as glutamine (Gln) and glutamic acid (Glu), carbohydrate, and ATP. Gln and Glu are involved in nitrogen assimilation [19], and together with asparagine, arginine, and tyrosine they made up more than 60% of the total amino acid concentration in five species of microalgae [20]. Among the crowded signals from 4 to 3 ppm it was possible to find chemical shifts characteristic of carbohydrate protons. Microalgae use various carbohydrates such as starch and chrysolaminarin as storage compounds, and sugars are abundant in cells when nutrients become depleted in the growth medium [21].

From the peak assignment in extract-sample spectra, it was possible to find coincident peaks in the HR MAS ^{1}H NMR spectrum for many different metabolites, including fatty acids, amino acids, and carbohydrates (Figure 1, Table 1). The differences between extract and whole-cell samples were small, although some shift differences can be expected since the chemical properties of the metabolites and their surroundings are changed when they are extracted from whole cells. Also, the application of pulse sequences to improve spectral features leads to a certain biasing of the data, such as the application of the CPMG pulse to partially suppress lipid signals in order to eliminate broad peaks. Furthermore, the differences in NMR properties of metabolites of varying size and in different cellular compartments leads to variation in magnetic properties and in some cases also “NMR invisibility,” which means that some metabolites are not registered in the whole-cell analysis [22]. This is seen from a close resemblance of whole-cell and hydrophilic-extract spectra (not shown), and from the knowledge that small molecules in liquid state are optimal for NMR analysis it is natural to assume that molecules in suspension in the cell will resonate clearly in the spectrum. The advantage of this feature is that it can be used to study compartmentation or distribution of metabolites in the cells.

The possible classification of microalgae species based on their specific HR MAS ^{1}H NMR spectra was investigated by application of two multivariate clustering techniques to a set of spectra from different algae [17]. The algae exhibit species-specific differences in cellular structure and size as well as chemical composition, and residual water is also varying between samples. Some signs of J-modulation due to spin echoes with too long interpulse delay could therefore appear in some spectral regions, but for the matter of comparison all spectra were acquired

using the same protocol. The multivariate clustering techniques principal component analysis (PCA) and fuzzy clustering (FC) were applied, since they reveal structures in the data without relying on assumptions such as the underlying statistical distribution. In PCA, which is a linear dimension reduction technique, systematic variation in a data set is extracted to a set of principal components (PCs) through the modeling of variance and covariance structure. In FC, the data are partitioned into fuzzy subsets and approximated by linear regression models, where the probability of a sample being member of a specific class is calculated based on the NMR characteristics and expected number of classes [23,24]. Selected parts of five replicate HR MAS ^{1}H NMR spectra of whole-cell samples of *Dunaliella* sp. (Chlorophyceae), *Amphidinium carterae* (Dinophyceae), *Phaeodactylum tricornutum*, and *T. pseudonana* (Bacillariophyceae) were used as input, and the best separation was obtained with the chemical shift region from 4 to 3 ppm. The three first PCs (of n possible) cumulatively accounted for 90% of the

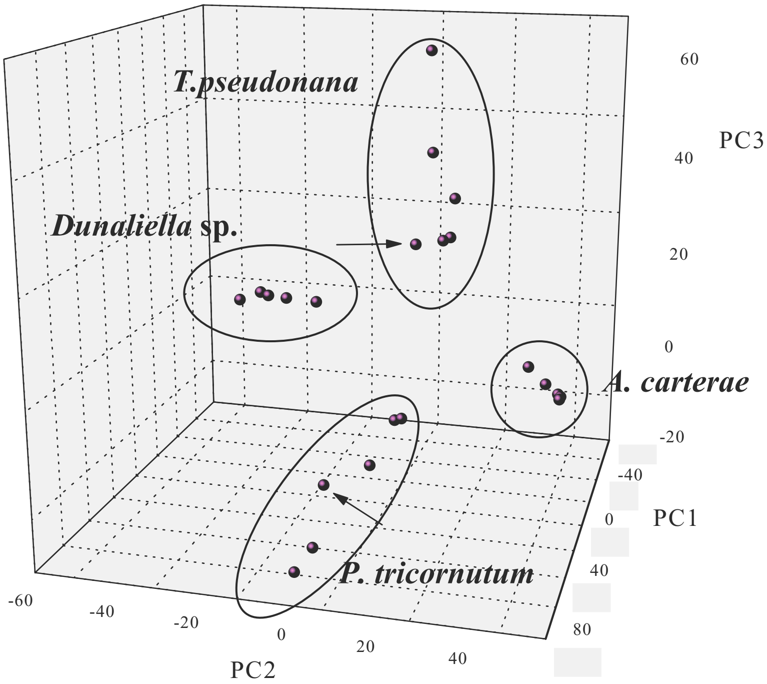

Fig. 2. Principal component analysis of HR MAS ^{1}H NMR spectra of four microalgae, where the three first Principal components explained 90% of the variance in the original data. The chore data set consisted of five replicate samples from each alga, and arrows indicate correct grouping of two additional samples from a separate experiment where the algae were grown using the same growth conditions and sample handling. Reproduced with permission from Inter-Research, original publication in Chauton *et al.* [17].

variance (Figure 2). A distinct grouping of the different microalgae was seen both in the PCA and in the FC, and to further test the replicability two spectra from a previous culture set up (but with the same growth conditions) were included. These spectra were also correctly classified, indicating robustness and reproducibility of the analysis.

The distinct grouping of algae in the PCA was analyzed further, and the peaks that were most important in determining the output were identified. Several metabolite markers were found: dimethylsulfoniopropionate (DMSP), betaine, glycerol, choline, and lactate. DMSP and betaine are osmolytes in many microalgae, while glycerol and choline have multiple cellular functions: in addition to being osmolytes, glycerol is a component of storage triglycerides and choline is incorporated into membranous phosphocholines. The distribution of microalgae in the score plot presented here was to a large degree coincident with reported findings on cellular content of the various compounds, which varied with growth stage and nutrient conditions [25]. The fact that osmolytes, which are relatively small molecules found in the cytoplasmic regions of the cells, determine the outcome of the PCA is again an indication of variations in NMR properties due to differences in molecular size and cellular distribution. Some recent studies showed that PCA and hierarchical cluster analysis of ^{1}H NMR spectra could be used to separate earthworm species [26] and multivariate analysis of ^{1}H NMR spectra was used in metabolic fingerprinting of the plant *Arabidopsis thaliana* [27]. Potts *et al.* [7] discussed the impact of NMR parameters on the PCA of rodent urine, while Defernez and Colquhoun [28] assessed the robustness of metabolic fingerprinting by ^{1}H NMR.

The use of HR MAS NMR spectroscopy in metabolic profiling and taxonomic discrimination of marine microalgae is very new, and our results show that it is a method with great potential. The application of ^{1}H NMR on biological samples benefits from the high natural abundance of these nuclei, and the analysis time can be reduced. On the other hand, since ^{1}H occurs in all organic molecules the resulting spectra may be crowded and poorly resolved. For more detailed studies of particular molecular groups such as fatty acids or carbohydrates the application of ^{13}C NMR can result in more detailed information, such as presented in the Part 2 of this work on microalgae.

Conclusion

HR MAS NMR analysis directly on whole-cell samples is a useful tool in metabolic profiling and taxonomic discrimination of marine microalgae, and the advantage of applying NMR instead of conventional methods such as bio-optics and HPLC is that many metabolites can be studied simultaneously in relatively short time, without any extraction involved. The use of NMR on such complex samples needs further studies, however, in order to clarify such things as differences in NMR-visibility of the different types of molecules depending on cellular location. Since there is little experience from NMR-studies on microalgae it is also important to investigate the contributions to any variability in the spectra, and separate natural biological variability from variability due to NMR properties.

Introduction

The use of HR MAS NMR presents a unique tool for studying biological solid and semisolid samples [1,2]. The method gives information on different classes of compounds from the samples in question that would have taken multiple analyses to obtain otherwise [3]. Due to the lower sensitivity of ^{13}C NMR in comparison to ^{1}H NMR, the latter would be the method of choice for studying small metabolites and osmolytes, and biological processes involving these. Reported applications of ^{1}H HR MAS NMR to study microalgae have been discussed by Chauton and in HR MAS NMR Spectroscopy, Part 1, found in this book on pages XXX–XXX.

Microalgae play a fundamental part in aquatic primary biosynthesis of important lipids, which include polyunsaturated fatty acids (PUFAs) [3]. Lipids and storage polysaccharides are products of important biochemical pathways, and the amount and composition of these compounds represent valuable information on the physiological status and biochemistry of microalgae [4,5]. Information on the overall degree of unsaturation of fatty acids may be obtained using ^{1}H NMR by comparison of resonances originating from the total allyllic and double allyllic and methylenic resonances [6], and n-3 fatty acids may be quantified [7]. The ^{1}H NMR spectrum does, however, give little detailed information with regards to individual fatty acids.

Storage polysaccharides are also important in microalgal biochemistry. The content of these may indicate the physiological status as it varies in response to growth conditions [8]. Polysaccharides may be studied by ^{1}H NMR to describe linkages and residue composition, but there are some limitations due to crowded spectra as the number of different residues and linkages increase [9]. The storage polysaccharide of diatoms is chrysolaminaran, which is a β-glucose polymer linked in β-(1→3), β-(1→6), and β-(1→2) positions [10]. The main chain of these polymers are β-(1→3) linked. Kim *et al.* have shown that ^{1}H NMR may be used to describe the polymerization and branching of these polymers by dissolving β-(1→3, 1→6)-glucans in d_6-DMSO [11]. When the polysaccharides are dissolved in D_2O or observed in whole cells with HR MAS the resolution of the spectra does, however, not allow for the same accuracy as the method of Kim *et al.*

Methods in which information on the fatty acids and polysaccharides of microalgae may be obtained simply and rapidly would be valuable for a wide array of purposes from the study of biological processes to nutritional value. Both for fatty acids and polysaccharides the resolution of the ^{13}C NMR spectrum provides good information both on composition and structure. The use of ^{13}C NMR in studies of fatty acid composition is widespread and well documented, and usages include content and composition of lipids [12]. The amount of available data make assignments in most cases a matter of comparing chemical shift values with the literature. For polysaccharides ^{13}C NMR is a powerful tool both for homo- and heteropolymers to describe both linkages and residue composition. Furthermore, the DEPT pulse sequence allows for discrimination between CH, CH_2, and CH_3 groups [13].

Both homo- and heteronuclear 2D techniques are powerful tools for studying both fatty acids and polysaccharides [14]. The use of these techniques is an invaluable tool for clarifying ambiguous assignments of peaks in 1D spectra when describing the linkages of storage polysaccharides in mixtures of compounds and cells. This chapter present results from a HR MAS NMR study on the marine diatom *Chaetoceros mülleri*, where the resonances belonging to fatty acids [15] and the storage polysaccharide chrysolaminaran were assigned with the use of literature values and spectra from extracted samples for both classes of compounds and 2D ^{13}C,^{1}H correlated spectroscopy for polysaccharides [16].

Results and Discussion

The ^{13}C HR MAS NMR spectrum of cells of the marine diatom *C. mülleri* show resonances belonging to both fatty acids and the chrysolaminaran storage polysaccharide (Figure 1). From this spectrum Chauton *et al.* [15] assigned the resonances originating from fatty acids by comparing the spectrum with a lipid extract recorded in chloroform from which the resonances could be compared with literature values. DEPT NMR was used to support the comparison of the HR MAS and liquid state spectra as small differences in the resonances frequencies (at the most 0.1 ppm) between the two were observed. The profiles of the two spectra, however, were the same. The essential PUFAs, EPA, and DHA were assigned along with the 16:1 and 20:4, which are fatty acids involved in the biosynthesis of PUFAs (Table 1) [17,18]. In addition to these assignments, resonances from PUFAs which could not be assigned to individual fatty acids were seen along with triglyceride and phospholipid resonances. The results represent the use of HR MAS NMR as a tool for studying microalgal biochemistry as well as for the purpose of determining nutritional value of microalgae. The fact that ^{1}H experiment is almost always done prior to recording ^{13}C experiments makes it possible to relate the ^{13}C analysis of the fatty acid content of the microalgae studied to the metabolite profile found in the ^{1}H experiments. This would give researchers employing the HR MAS method unique opportunities to have information on biochemical processes related to fatty acid biosynthesis from the same sample with only one simple sample preparation; just collect the sample by centrifugation, add deuterium oxide, and insert the sample in the MAS rotor.

The chrysolaminaran peaks found in the ^{13}C HR MAS spectrum were assigned by Størseth *et al.* [16] primarily from ^{13}C-DEPT NMR and ^{13}C,^{1}H-correlated spectroscopy (HETCORR) (Figure 2). β-(1→3)-Glucan resonances are found in the 60–105 ppm region of the ^{13}C NMR spectrum. As other resonances were found in this region making unambiguous assignments difficult directly from the 1D spectrum. The use of the 2D heteronuclear

$^{+}$Overlaps with glucose C-6.

spectrum allowed the structural characterization of the β-1→3 glucan of *C. mülleri* as the non-glucan resonances could be excluded on the basis of their ^{1}H correlations. Non-glucan resonances which overlapped with glucan resonances were also easily detected by this method and this excluded misinterpretation of the structure of the glucan. The assigned resonances from the glucan and non-glucan peaks are shown in Table 2 together with the resonances from glucose some of which overlapped with the glucan resonances.

The extracted glucan was analyzed by the method of Kim *et al.* [11], using ^{1}H NMR in DMSO to give information on the DP and DB of the glucan. Results from this analysis showed some (1→6) linkages, and the glucan was found to have a DP and DB of 19 and 0.005, respectively. As the bonded and non-bonded C-6 of the glucopyranosyl residues have different chemical shifts and also using the DEPT135 pulse sequence, have opposite signs to C-1 through C-5 the presence of (1→6) glycosidic linkages in glucans may easily be detected. However, in the case of the HR MAS analysis of the *C. mülleri* cells this was not observed. This could be attributed to the low DB and the fact that the sensitivity of the ^{13}C analysis is low compared to the ^{1}H analysis. Results obtained from the HR MAS analysis of the glucan cells indicated that it is possible to obtain the structure of the chrysolaminarans directly without extraction. The limitations are linked to the detection of branches when these are few compared to the number of molecules and the DP of the molecules.

Conclusion

The papers which have formed the basis of HR MAS NMR spectroscopy of marine microalgae (Part 1 and 2 in this book) present the possibilities and potential of using HR MAS NMR as a tool for studying biochemical processes and chemical composition in microalgae. The works with ^{1}H NMR have to a great extent been based on tentative assignments from comparison with literature data when considering metabolite analysis directly on

whole cells, while the identification of fatty acids by ^{13}C NMR was done by way of comparing the obtained results with literature values after extraction. The analysis of the β-glucan of *C. mülleri* presented by Størseth *et al.* [16] was verified by the analysis of extracted β-glucan by established methods. These are possibilities that should be examined further, and should lead to simplified analysis techniques giving extensive information on microalgae in general, not just the species presented in these studies.

[2]*St. Olavs Hospital, N-7465 Trondheim, Norway*

Introduction

Although being less sensitive than many other analytical methods, magnetic resonance imaging (MRI) does have significant advantages such as being non-invasive and non-destructive. Furthermore, no sample preparation is needed prior to analysis and the method is not hampered by limitations regarding signal penetration depth. However, due to the high investment costs, the sheer size of the instrument and the necessary related infrastructure, MRI cannot presently be considered as a standard analytical tool in aquaculture or fish processing industry. As a research tool, however, taking advantage of the unique features of the method, we can obtain basic insight into a number of issues related to anatomical studies, composition and structure of tissues, distribution maps of fat, water, and salt as well as temperature profiles (mapping). Moreover, theoretical transport models can in turn be used to interpret the images. For the aquaculture industry, MRI studies may for instance be helpful to study the effect of feed composition (fat) and different feeding regimes on fat contents and distribution in tissues. In fish processing, MRI can be used as a tool for the optimization of various unit operations such as salting, freezing, and thawing. For a more detailed treatment of various MRI applications, see review by Hills [1].

MRI is a technique that offers a unique opportunity to "look inside" intact whole organisms, i.e. to produce high-quality cross-section images. Depending on the particular task, MRI instruments can produce several types of contrast images. This is achieved by programming and running specific MR sequences to make it possible to differentiate between protons in molecules having different mobilities or chemical environments. For example, it is possible to obtain MR images of "water" and "fat" [2], "diffusion weighted" images where only molecules with low mobility are visible [3] or high resolution images of connective tissue [4]. Contrast agents—administered to the circulatory system—added to affect relaxation times are often used in connection with medical *in vivo* examinations to obtain a specific MRI contrast [5]. MR images of water and fat in burbot (*Lota lota*) liver have been acquired. The MR signal intensity in the reconstructed images showed good correlation with the liver fat content in live fish. Significant correlations were also obtained for water and protein contents [2]. Collewet *et al.* [6] proposed to use MRI as a tool to assess fat distribution in fish. It was shown that higher contrast between muscle and adipose tissues can be obtained when the MR images are highly longitudinal relaxation time (T_1) weighted. Moreover, based on comparison with chemical analysis of fat, better correlations with quantitative MR data were obtained by accounting for coil sensitivity and radio frequency (RF) field inhomogeneity. Compared with fresh cod (*Gadus morhua*), Howell *et al.* [7] reported that MR images of fish stored for 6 weeks at -30°C were not different. In contrast, images obtained from fish stored at -8°C exhibited dense lines indicative of tissue gaps. Fresh rainbow trout (*Salmo gairdneri*) was subjected to freezing–thawing before MRI analysis to visualize various organs, and to identify spatial distributions of lipid- and collagen-rich tissues. T_1-weighed images were clearly shown to highlight the lipids relative to water containing tissues. On the other hand, transverse relaxation time (T_2) and magnetization transfer (MT) contrasted images showed the clearest distinction between muscle tissues [8]. The effect of freezing and thawing of a lean species (cod) and a fatty species (mackerel, *Scomber scombrus*) was studied by Nott *et al.* [9]. In particular, the T_1^{sat} (measured during saturation transfer) and MT rate were shown to be sensitive parameters to assess the effects of frozen storage. Compared with fresh fish, the freezing–thawing cycle of both species induced increased MT rate and T_1, whereas T_1^{sat} decreased. The same effect was consistently observed with increasing frozen storage time (2–12 weeks). Foucat *et al.* [10] used a cylindrical sample carrier in the MRI magnet allowing six frozen–thawed trout (frozen storage for 0–41 days) and reference tubes to be analyzed simultaneously. An image containing information about anatomical features, MT ratio, T_2, and diffusion constants (parallel and perpendicular to muscle fiber orientation, $D\perp$) were acquired in 5 min. Compared with fresh fish, the freezing–thawing cycle significantly affected only the mean T_2 and the $D\perp$-values, which changed from 42.3 to 47.1 ms and

Graham A. Webb (ed.), Modern Magnetic Resonance, 959–966.
© 2008 *Springer.*

from 0.85×10^{-5} to 1.07×10^{-5} cm^2/s, respectively. Only $D\perp$ was affected after frozen storage for 41 days. The increase in T_2 was attributed to protein denaturation (during freezing–thawing) leading to redistribution of water within the muscle tissue. Concomitantly, with the appearance of extracellular spaces between fibers, the migration of water increased in a direction perpendicular to fiber orientation.

Regarding aquatic organisms, the feasibility of using MRI for anatomical studies was first demonstrated by Blackband and Stoskopf in 1990 [11]. When using *in vivo* localized MRI, it was possible to distinguish between different organs such as muscle tissues, gills, spine, stomach, and uterus in embryonic fish [12]. Post-processing of MR multi slice data makes it possible to obtain three-dimensional (3D) maximum intensity projection maps (MIPs) or surface projection maps of the organism (e.g. spider crabs, *Maja squinado*) [13]. Another technique that may be considered is the double-quantum filtered MRI where only molecules associated with ordered tissue structures are detected by suppressing the signals from isotropic fluids [14].

The goal of the present study was to demonstrate some MRI applications which may be of interest in aquaculture, fish processing, and quality control.

Materials and Methods

All MRI studies presented here were carried out using the Bruker Avance DBX100 instrument (Bruker Optik GmbH, Germany). The magnet has a horizontal wide bore opening suitable for imaging of comparatively large objects (^{1}H imaging area—sizes up to 15 cm in diameter and 15 cm in length).

Spatial Distribution of Fat and Water in Atlantic Salmon Fillets

To visualize the spatial distribution of fat and water in an Atlantic salmon (*Salmo salar*) fillet, a chemical shift selective (CHESS) MRI protocol was used. Three image types of a fillet piece ($3 \times 3 \times 4$ cm) were acquired: "a proton density image," "a fat image," and "a water image." The following acquisition parameters were used: matrix size = 128×128, relaxation delay (T_R) = 2 s, number of excitations (NEX) = 40, number of slices = 25, and echo times (T_E) = 9.1 (fat selective images) and 26.4 ms (water selective images). For the fat excitation, a selective sinc-shaped pulse with a bandwidth of 1200 Hz was centered 400 Hz (+200 Hz) away from the water signal frequency to avoid signal contribution from water. For the water signal excitation, a similar sinc pulse with a bandwidth of 480 Hz was centered at the water resonance frequency (−200 Hz) to avoid signal contribution from fat. The "proton density" image was acquired using a Multi-Spin Multi-Echo (MSME) protocol with $T_E = 7.2$ ms, $T_R = 2$ s, and NEX = 4. The total acquisition times were 2 h 51 min for the CHESS protocol and 17 min for the MSME protocol. Sufficient suppression of either the fat or water spectral component could only be achieved in a region with highly homogeneous magnetic field (limiting sample size under study) and RF pulses. Thus, careful shimming prior to image acquisition was necessary.

Distribution and Determination of Water and Salt in Cod Fillets

Sample preparation and brine salting procedure is described elsewhere [15]. For the determination of water and salt contents in the cod fillet an MSME imaging protocol was used. The protocol parameters for the ^{1}H MRI experiments were matrix size = 128×128, $T_R = 3$ s, NEX = 2, and number of slices = 3. The experiment was repeated five times with incremented echo times of 9, 18, 27, 36, and 45 ms, thus producing a set of five T_2 weighted images of each slice. To quantify the ^{1}H image, a reference solution with known water content and a relaxation time similar to that of the fish was prepared and imaged along with the sample. This was accomplished by mixing distilled water with deuterium oxide (D_2O) in known weight proportions. As deuterium compounds are ^{1}H MR silent, mixtures with water can be used to simulate homogeneous systems with predetermined water contents. The mixture was doped with 0.001 mol/l $MnCl_2$ to shorten the T_2 relaxation time to approximately equal to that of the fish muscle. The reference solution contained 64 wt% water with a relaxation time of 27 ms.

An in-house made 60 mm ^{23}Na RF volume coil was used for the salt studies. The ^{23}Na imaging protocol with the following parameters was employed: matrix size = 64×64, $T_R = 250$ ms, NEX = 64, and number of slices = 1. The experiment was repeated six times with incremented echo times of 2.7, 4.7, 6.7, 8.7, 10.7, and 12.7 ms. A ^{23}Na image of a slice, 20 mm in thickness, was acquired for each sample with a 1 mm spatial in-plane resolution. The acquisition time per sample was 6 min. For the sodium quantification from the salt images, a reference solution (18% NaCl) was imaged with the fish sample.

To quantify MR images, the average signal intensities of the fish samples and reference solution were determined by geometrically defining a region of interest (ROI). The mean intensity of all pixels within two selected ROIs were then calculated. The calculated average intensities for the fish and reference solution ROIs were plotted as a function of echo time on a semi-logarithmic scale. The initial amplitudes of the T_2 relaxation curves for the fish (M_{fish}) and the reference solution (M_{ref}) were obtained by extrapolating this curve to zero time using a monoexponential function, thus taking into account differences in the relaxation time between the fish and the reference. The calculated amplitudes were proportional to the average water content in the selected ROIs. The fish (ROI) water content was then calculated as

$$W_{\text{fish}} = W_{\text{ref}} \times \frac{M_{\text{fish}}}{M_{\text{ref}}} \quad (1)$$

where W_{ref} was the water reference solution described above. Likewise, the salt content of the same samples was calculated from the corresponding salt images. In this case, W_{ref} the sodium reference solution was used.

Freezing of Atlantic Salmon and Cod Fillets

A temperature regulated nitrogen blast-cooling device was built to regulate the temperature in the magnet. Two different freezing regimes were studied by MR imaging (i) a dynamic study where the fish sample temperature was reduced while MR images were acquired and (ii) a study at several constant temperature conditions. While the dynamic study represented typical industrial freezing conditions, the study at constant temperature conditions allowed to extract more information and made it possible to determine the fraction of unfrozen water at each temperature.

(i) In *the dynamic freezing regime study*, cylindrical fillet pieces of cod and salmon white muscle (diameter 2.8 cm, length 3 cm) were studied at the temperature ranges from +10 to –10 °C (cod) or –30 °C (salmon). The samples were wrapped in plastic foil to prevent loss of liquid. The freezing procedure was to instantaneously expose the samples to nitrogen gas flow with a preset flow rate and temperature. The temperature in the sample was monitored using a thermocouple which was removed from the RF coil during image acquisition. Due to very short transversal relaxation times at low temperatures, the broad line imaging package (BLIP) was applied to be able to obtain the short echo times. The acquisition parameters were $T_E = 2.6$ ms, $T_R = 700$ ms, NEX = 4, slice thickness = 3 mm, matrix size = 64 × 64, and field of view (FOV) = 4 cm, giving spatial image resolution of 63 μm. The time interval between successive images was 3 min. The dynamic experiments were started at 10 °C and the variation of the mean image intensity of the selected ROI (covering the whole sample cross-section) was measured as a function of freezing time.

(ii) At *constant temperature conditions*, the temperature was stepped through a range of preset values (with steps varying from 2 to 4 °C). The temperatures were measured with an accuracy of ±0.1 °C at each step. The time delay for the temperature to stabilize at each step was varying depending on the temperature. The experiment was carried out in the same temperature ranges as the dynamic freezing studies. The same imaging protocol (BLIP) and MRI parameters were also used in this case for acquiring the "proton density" images. To calculate the spin density it was necessary to measure both T_1 and T_2 relaxation times at each temperature. Due to the short value, the T_2 relaxation time was measured with a series of BLIP spin echoes by varying the echo time. The T_1 relaxation time was measured with a series of BLIP inversion recovery experiments by varying the inversion time. Relaxation time measurements and the corresponding spin density calculations were carried out at constant temperatures only.

Anatomical Defects in Farmed Atlantic Salmon

The MRI technique can non-destructively visualize fish structure, providing by various types of contrast between the backbone, water in muscle, fat, and connective tissue. Here, the MRI technique was applied to study the fish backbone structure aiming at revealing the reason why backbone deformations occur under different fish farming conditions.

Six farmed Atlantic salmon (weight 2.8 ± 0.6 kg and condition factor 2.1 ± 0.3) were collected after slaughtering at a commercial fish processing plant. The fish were downgraded due to visible backbone deformities. The fish were frozen and kept at −20 °C until analysis. Prior to the MRI measurements, the fish were thawed at 4 °C overnight. For the anatomical studies, a MSME T_1-weighted imaging protocol was used with the following parameters: $T_E = 20$ ms, $T_R = 400$ ms, 6 slices, NEX = 4, and FOV = 13 cm.

Results and Discussion

Spatial Distribution of Fat and Water in Atlantic Salmon Fillets

In the conventional "proton density" MR image, both fat and water components exhibited maximal intensities (Figure 1a). Even so, the major fat deposits in the myosepta (light "stripes") could clearly be identified. This corresponds with the typical lipid storage pattern within Atlantic salmon fillets [16]. The CHESS imaging modality makes use of the fact that the protons in fat and water molecules have slightly different resonance frequencies and hence they will have different chemical shifts. When using the method, a frequency selective RF pulse with a predefined bandwidth is applied to excite either the fat or the water spectral component only. This made it possible to achieve good separation between the two components and thus high-quality "fat" (Figure 1b) and "water" (Figure 1c) images could be acquired. In fish muscle, the sum of water and fat is fairly constant at about

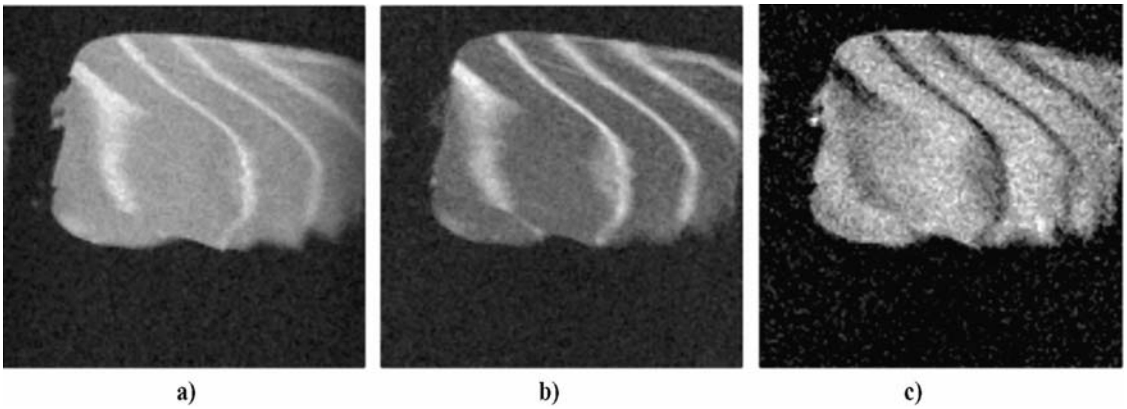

Fig. 1. MR images of an Atlantic salmon fillet piece: (a) "Proton density image" where both water and fat protons were visible. Regions with brighter pixels originated from high fat areas, while the darker pixel regions originated from water, (b) "Fat image" acquired by selective RF excitation of fat protons only. No water protons contributed to the pixel intensities, and (c) "Water image" acquired by selective RF excitation of water protons only. No fat protons contributed to the pixel intensities. The acquisition times were (a) 17 min and (b, c) 2 h 51 min.

80%. With this in mind, we can clearly see that in areas with high fat content, the water content was lower—and vice versa—in areas with low fat content, more water was observed.

Distribution and Determination of Water and Salt in Cod Fillets

In a multi-echo imaging experiment, echo time can be thought of as a certain time delay between the excitation pulse and spin-echo observation moment. During this delay, the net magnetization of nuclear spins slowly deteriorates, causing T_2 relaxation. This process results in a decrease of the signal intensity in each image pixel at a rate inversely proportional to the relaxation time in the pixel. This is clearly seen in Figure 2 showing ^{1}H images of a cod fillet piece acquired using incremented echo times of 9, 18, 27, 36, and 45 ms. Regarding the visual appearance of water distribution in the images, the best contrast was obtained at the shortest echo time. "Water and salt images" (echo time 9 ms) of three cod fillet pieces (one slice) are shown in Figure 3. It is clearly seen that when using the current salting method, the distributions of both water and salt were inhomogeneous. This is in accordance with a previous study using a similar cod salting procedure [15]. When comparing "the water and salt images" pairwise, the distributions (signal intensities) of the two components seem to correspond quite well, i.e. in areas with high water content, the salt content was also high (bright regions). The darker regions, with lower water and salt contents, may be explained by reduced diffusion rates due to different tissue composition or structure. The relative uncertainties in the determination of both variables were estimated to be about 1.5%. Due to the inhomogeneity of the water and salt distributions, a better estimate of the contents in the whole sample was achieved by manually choosing the ROI covering the whole sample (Figure 4a). Figure 4b shows the monoexponential extrapolation of

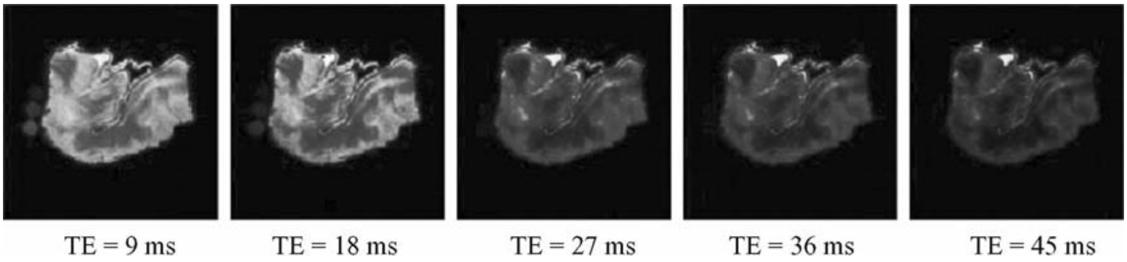

Fig. 2. A set of five T_2-weighted ^{1}H images of a cod fillet piece acquired at five incremented echo times.

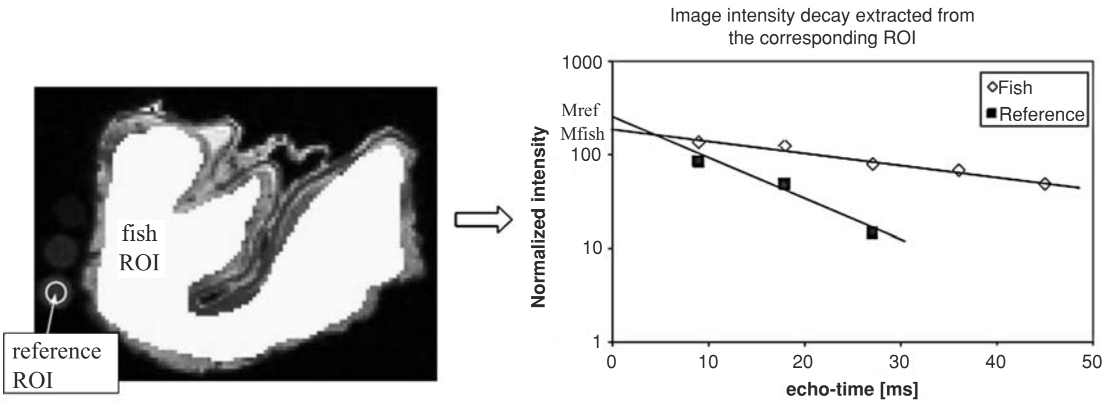
decay curves to zero time to determine total water and salt contents in the sample (M_{fish}). The mean water and salt contents, as well as the lowest and highest values are summarized in Table 1.

Regarding quantitative NMR detection of ^{23}Na nuclei, it should be kept in mind that partial NMR "invisibility" of the sodium nuclei is sometimes reported. The effect can be ascribed sodium nuclei having an electric quadrupolar moment which causes rapid multiexponential relaxation. In biological systems, the binding of a certain fraction of sodium ions to macromolecules (proteins), will render them immobile and thus NMR "invisible." In both cases,



a)

b)

Fig. 4. (a) Selected regions of Interest (ROIs) in fish sample and reference and (b) monoexponential extrapolation of the decay curves to zero time was used as a measure of the total contents of water or salt in the sample (M_{fish}).

Table 1: Mean water and salt content in cod fillet pieces calculated from the three MR slices images (see Fig. 3 and 4). The corresponding variation ranges (minimal and maximal contents) are given in the parentheses.

Sample	Water content (wt %)	Salt content (wt %)
1	54 (47–62)	14 (9–17)
2	58 (55–61)	12 (7–14)
3	54 (49–65)	13 (8–18)

the estimated sodium concentrations may be too low. It seems as the experimental conditions have significant effects on these phenomena [15,17].

Freezing of Atlantic Salmon and Cod Fillets

Dynamic Freezing Regime Study

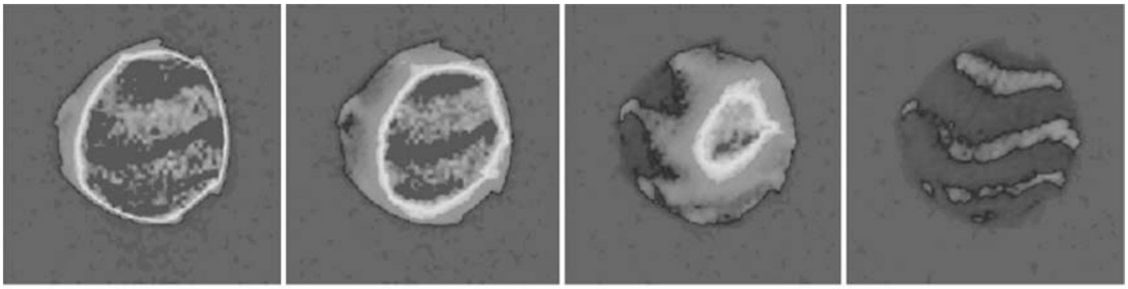
Figure 5 shows four MR images from a freezing series of the dynamic study of Atlantic salmon white muscle corresponding to about 13, 19, 28, and 37 min after start of cooling. Initially, the mean ROI signal increased, then an intermediate maximum was observed, and finally decayed as the temperature decreased. When the image analysis was performed on narrow circular concentric ROIs, it was observed that: (1) prior to the formation of a "freezing front" the signal rose uniformly throughout the sample; (2) once the "freezing front" was formed at the sample surface, the intensity of interior ROIs remained constant at the maximum value, until (3) the "freeze front" passed leading to a rapid signal decay. Since cod muscle has very low fat content (~0.3%), the corresponding MR images showed the muscle water only. On the other hand, the typical fat content in salmon white muscle is 8–23% [18] meaning the images show the distributions of both fat and water. From the images it was observed that in the areas of fat deposition, freezing was not complete at –30 °C (Figure 5). This is in accordance with previous NMR studies of fat mobility at low temperatures [19].

Constant Temperature Conditions

In Figure 6a, the T_1 and T_2 relaxation times for a cod sample are shown. The measured signal (S) from the images is given by

$$S = \rho \times e^{-\mathrm{TE}/T_2}(1 - e^{-\mathrm{TR}/T_1}) \qquad (2)$$

from which the spin density (ρ) can be calculated. According to Curie law, the true density of protons (ρ_0) is modulated by a factor $1/T$ to give the observed spin density as follows: $\rho \propto P_0/T$ [20]. The ice is MRI-invisible ($T_2 \sim 0.01$ ms). Therefore, to determine the fraction of unfrozen water (= 1.0—ice fraction), the calculated spin density was multiplied with the absolute sample temperature (T) and then normalized by the spin density above the freezing point. The calculated fraction of unfrozen water as a function of temperature is shown in Figure 6b. It is seen that below the freezing point, T_1, T_2, and the unfrozen water fraction decreased rapidly with the temperature. At each temperature step below the freezing point, a certain fraction of water froze (gradual freezing point depression) and thus became MRI-invisible. At the same time, the remaining unfrozen water fraction relaxed faster. In accordance with the signal increase observed prior to the passage of "the freeze front" in the transient studies, both the reference image signal and the calculated spin densities increased upon cooling above the freezing point. Furthermore, the calculated water fraction at stationary conditions was close to unity above the freezing point. Therefore, the signal change in this temperature range could mainly be attributed to the Curie law. Another factor contributing to this effect was the increase of the T_R/T_1 ratio as the temperature was reduced. Due to the low signal-to-noise ratio in the images it was not possible to determine relaxation times and thus perform the spin density calculations at a pixel level. By improving



13 min 19 min 28 min 37 min

Fig. 5. MR images of a dynamic freezing study of an Atlantic salmon fillet piece. At 37 min the temperature had reached –30 °C.

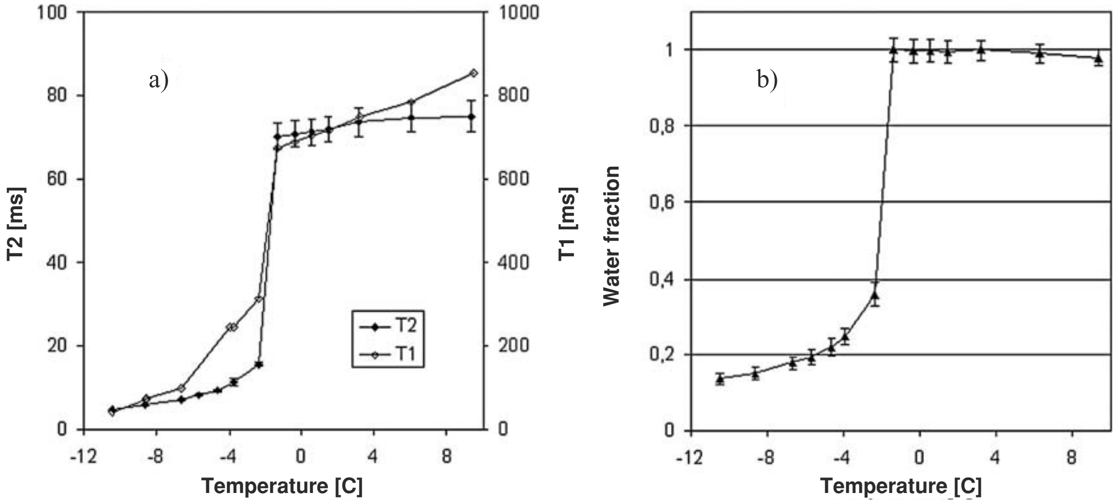


Fig. 6. (a) Constant temperature freezing study. Longitudinal (T_1) and transversal (T_2) relaxation times in a cod muscle piece at different temperatures and (b) calculated unfrozen water fractions at different temperatures. The observed tissue freezing temperature zone was from −2.35 to −1.35 °C.

the experimental technique, the calculation of both ice content (fraction) and sample temperature maps at a pixel level may be achieved. For salmon it was observed that the water component froze as rapidly as in cod, while the fat component signal decreased with temperature much more slowly. Quantification of the salmon images would therefore require separate water and fat analyses.

Summing up, the MRI technique clearly distinguished between frozen and unfrozen regions in fish tissues. At stationary freezing conditions, the fraction of unfrozen water in cod muscle could be calculated as a function of frozen storage temperature. Further development of the method may concentrate on the quantification of the dynamic set of images at pixel levels and on the determination of the speed of "the freezing front" propagation. Ultimately, a 3D reconstruction from a multislice dynamic MRI study under controlled thermal conditions may provide valuable information to optimize the freezing and thawing processes.

Anatomical Defects in Farmed Atlantic Salmon

Figure 7 shows a MR image of one of the six investigated Atlantic salmon acquired sagittally through the middle of the backbone. The deformation of the backbone structure is clearly seen here and several deformed and partially missing vertebrae in the middle and lower part of the backbone can be identified. Similar backbone deformations, but at different locations along the fish were observed in the five other fish.

Conclusions

Determination fat, water, and salt contents including their spatial distributions in (processed) fish tissues can be done readily using MRI. Although quantitative MRI can

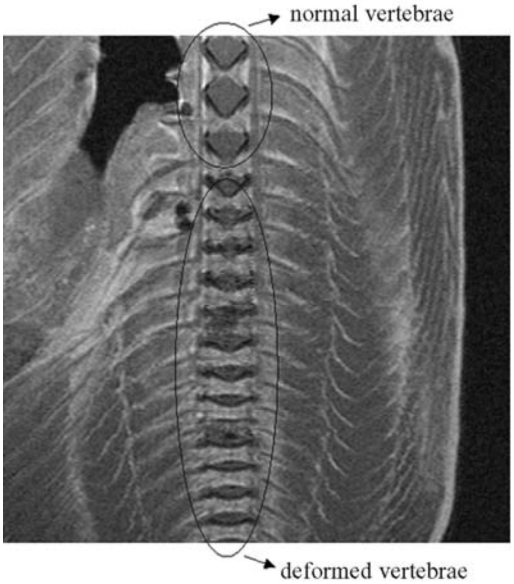

Fig. 7. An MR image of the middle section an Atlantic salmon revealing deformity of the backbone structure.

hardly be considered an alternative to chemical analysis presently, the method does offer a number of advantages compared with other analytical methods. As a research instrument however, we have demonstrated that MRI can be used to extract valuable results related to tissue composition, bone structure, and fish processing (salting and freezing).

How is the Fish Meat Affected by Technological Processes?

Loïc Foucat,[1] Ragni Ofstad,[2] and Jean-Pierre Renou[1]

Introduction

Because food is so important for survival, food preservation is one of the oldest technologies used by human beings. The fish preservation techniques mostly used today are salting and freezing. Salting is an ancient preservation technique. Salting keeps on being used, but it is often replaced by freezing. Smoking merely adds flavour and colour and removes some water. Smoked fish are almost as perishable as fresh fish.

Smoked fish are more and more consumed in Europe. Compared to other foods, they may contain considerable amounts of salt. Health authorities advise to reduce sodium-intake to the general population and especially to certain risk groups of consumers. Besides, the most common consumer complaint for these foods addresses their salty taste.

Modern trends in manufacture are to lower the final salt levels to meet consumer demands, to produce less desiccated products.

To investigate the effect of two technological processes (freezing/thawing and salting) on the fish (*Salmonid*) meat quality, Magnetic Resonance Imaging (MRI) and Magnetic Resonance Spectroscopy (MRS) were used. Authentication of fresh fish is of great importance to the consumer, the trading of frozen-thawed products as fresh being a frequent fraudulent practice. In previous studies, MRI protocol differentiates unfrozen from frozen-thawed fish, by determining the T_2 relaxation time and the diffusion coefficient of water [1–2]. The diffusion coefficient perpendicular ($D_\perp$) to the muscle fibre orientation axis allows an easy distinction between fresh and frozen trout. In comparison with fresh trout, the value of $D_\perp$ increases by 25% with freezing. It can be explained by the formation of gaps between fibres during frozen storage.

The salting process can be analyzed by NMR of proton to determine the density and mobility of water by measuring the relaxation times and diffusion coefficients and also by ^{23}Na and ^{35}Cl NMR. Thus, NMR offers a unique opportunity to access non-invasively the distribution and the state of Na^+ and Cl^- ions in tissues [3–4,5]. Both these NMR approaches allow to correlate the fluxes of water and ions in fish meat during salting [6], and also to determine the effect of raw fish (fat content, freshness . . .) on the salt distribution.

Two studies were presented in this chapter. The first describes how single quantum (SQ) and multiple quantum filter (MQF) can be used to determine the interactions of Na^+ and Cl^- ions with meat structure according to the technological process. The second study deals with the effect of size of fish on salt distribution.

Study of Salt Interaction in Smoked Salmon by SQ and DQF MRS

Multiple quantum filter NMR spectroscopy is particularly well suited to the study of ordered biological tissues. An MQ filter deletes the NMR signal belonging to isotropically reorienting ions, leaving only the signal from ions exhibiting biexponential decay (bound or entrapped ions). To characterize the dynamics of these two quadrupolar nuclei ($I = 3/2$), SQ and double quantum filter (DQF) acquisitions were used on smoked salmon.

Experimental

Smoked salmon fillets were obtained from IFREMER. Two different salting procedures were used: dry salt and brine injection. For each process, salting was designed to obtain three expected salt content of 2, 3 and 4% (w/w). A cylinder of smoked salmon (10 mm in diameter) was cut from the fillet and inserted into the NMR tube. For each salting process and salt content, NMR experiments were repeated on the series of five fillets, which results in a total of 30 samples.

NMR experiments were performed at 106 MHz (^{23}Na) and 39 MHz (^{35}Cl) on a Bruker DRX 400 (9.4 T). A 10 mm ^{23}Na/^{35}Cl double tune NMR probe was devised for this investigation. Samples were maintained in the spectrometer at 4 °C. For the overall NMR acquisitions, recycle times of 200 and 100 ms were used for ^{23}Na and ^{35}Cl nuclei, respectively. Aqueous solutions of $Na_7Dy(PPP)_2$ and $DyCl_3$ were prepared and used as external references

Graham A. Webb (ed.), Modern Magnetic Resonance, 967–971.
© 2008 *Springer.*

(5 mm NMR tube placed inside the 10 mm tube containing the sample studied) for sodium and chloride ion quantification, respectively. The $Dy(PPP)_2^{7-}$ and Dy^{3-} ions induced an upfield shift of Na^+ ($\Delta Na = 30$ ppm) and a downfield shift of Cl^- ($\Delta Cl = -55$ ppm) [7]. To characterize sodium chloride and water dynamics, ^{23}Na and ^{35}Cl longitudinal relaxation times, and ^1H transversal relaxation time were also measured with inversion recovery and CPMG sequences, respectively.

Results and Discussion

Figure 1 displays the linear relationship between the longitudinal relaxation time of sodium and chloride ions with the transverse relaxation time of water proton for the 30 samples studied. This indicates that dynamics of Na^+, Cl^- and water molecules are quite correlated. The injection process induced an increase in all relaxation times. The formation of small brine pockets in tissue structure associated with injection process could partly explain this increasing. This can be related to the difference in dry matter values obtained for the two processes: 32 and 27% for the dry salt and the injection, respectively.

To quantify the proportion of Na^+ and Cl^- bound ions, the DQF signals were quantified relative to the SQ signals, as previously described [8]. For the two salting processes, results are summarized in Figure 2. Statistically, there is no significant difference in bound fractions with salt content or process for each ion. Nevertheless, for the case of the injection process, there is a tendency for the bound ion contents to increase with salt concentration. Whatever the process considered, the proportion of bound ions is systematically greater for Na^+ than for Cl^-. Some hypothesis to explain this result can be differences in: ion endogenous concentration or/and ionic strength or/and ionic volume, which is more important for Cl^-.

From NMR parameters, salting processes were discriminated (Figure 3). The first axis in Figure 3 discriminates the process while the second axis the salt content.

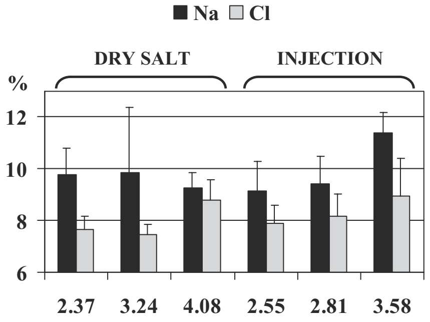

Fig. 2. Fractions of sodium and chloride bound ions for the two processes as a function of the percentage of salt. Mean values and standard deviation (n = 5).

MRI Study of Salt and Fat Distribution in Smoked Salmon

To investigate the effect of the fat content on the heterogeneity of salt distribution in smoked Atlantic salmon fillet, fish of two different sizes were dry-salted 5 days post mortem by the use of granulated (Ø 600 μm) mineral salt and thereafter smoked. The small fish, weight 1–2 kg, were salted in 1 h and 10 h and the large fish, weight 4–5 kg, were salted in 3 h and 13 h for the left and right hand fillets, respectively. Each fillet side was divided in two parts, the anterior section was cut from about 4 cm behind the front edge of the fillets and the posterior section was cut from about 4 cm in front of the edge of the tail. The length of the sections was 6 cm and the dorsal side was trimmed to a section width of 10 cm. For each of the two sections, MR-images were recorded in slices of 2 mm thickness at four positions, three in the ventral side of the lateral line and one in the dorsal side. MRI experiments were repeated on series of four fish for each of the two sizes, i.e. total 128 samples.

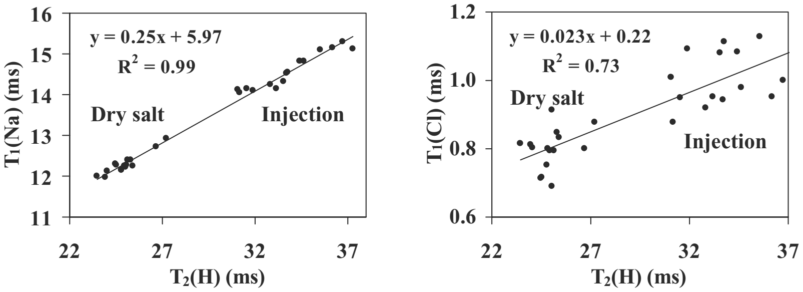

Fig. 1. Relationships between $T_1(Na)$, $T_1(Cl)$, and $T_2(H)$ for the 30 salmon samples studied.

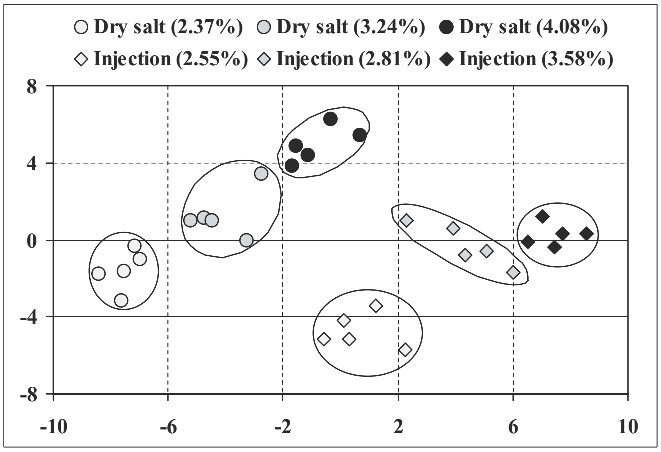

Fig. 3. Discrimination between salting process by Factorial Analysis.

MRI Experiments and Data Analyses

MRI experiments were performed at 200 MHz (^{1}H) and 53 MHz (^{23}Na) on a Biospec 47/40 Bruker (4.7 T). An 110 mm ^{1}H/^{23}Na double tune NMR probe was designed for this study. Water and fat images were recorded using multiple slice chemical shift selective inversion recovery [9]. T_2 water images with fat suppression were obtained from multi-mono-echo acquisition (7 echo time ranging from 15 to 120 ms). A gradient echo sequence was used for sodium imaging ($T_E = 3.2$ ms, $T_R = 100$ ms, 256 scans).

In order to identify the effect of the design variables, fish size, salting time, part and acquisition position a partial least-squares (PLS) regression model [10–11] was calculated using the design variables as X-values and the NMR parameters described above as Y-values. The size (small and large); the salting time (short and long); and the part (posterior and anterior) were valued 0 and 1, respectively, whereas, the acquisition position (Slice) were valued 0–3, from the ventral to the dorsal side of the fillet section. The multivariate models were validated by full cross-validation. All calculations were performed in The Unscrambler® Ver. 8.05 (Camo, Norway).

Results and Discussion

Examples of fat suppressed, water suppressed, and sodium magnetic resonance images of one of the sample sets are shown in Figure 4. The gross structural organisation of the fish muscle, i.e. muscle segments separated

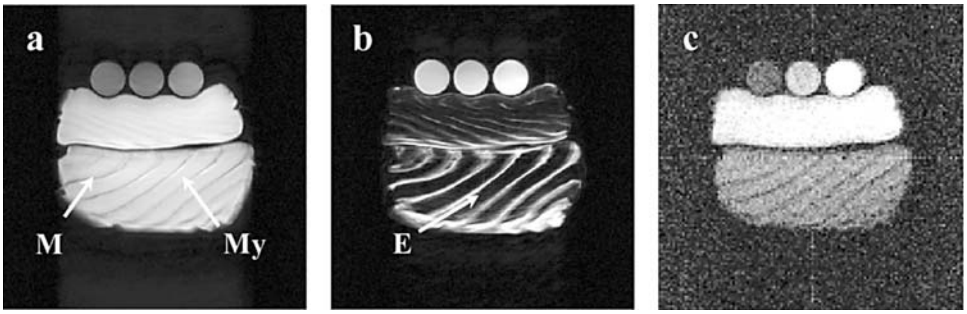

Fig. 4. (a) Fat-suppressed, (b) Water suppressed and (c) ^{23}Na MR-images of salted-smoked Atlantic salmon (weigth-4–5 kg). Top; lateral section (skin side down) of posterior part salted 13 h and Bottom; lateral section of anterior part (skin side down) salted 3 h. M; muscle segments (myotomes), My; Myocommata, E; endomysial sheath. Reference tubes (on the top) contain NaCl-solutions of 1, 2.5, and 5% from the left to the right hand side, respectively.

by myocommata is clearly visible in all the images. The distribution of fat is visualized as light areas in Figure 4b. Fat are within the connective tissue in the myocommata, but also thin light treads representing fat in the membrane and/or in the endomysial sheaths surrounding the muscle cells can be distinguished in the anterior part.

This part contains more fat than the posterior part and there is more fat in the skin side than in the belly side of the fillet. As expected, the fillet being salted for the longest period has the highest salt concentration (Figure 4c). The ^{23}Na-image also shows that the sodium distribution in the fillet is inhomogeneous. In the anterior part with the low salt content, the myocommata can be distinguished indicating that the salt concentration is lower in the connective tissue than in the myotomes. Moreover, the salt concentration is lower in the skin side of the fillet than in the belly side.

Figure 5 shows the correlation plot for Factor 1 vs. Factor 2 from a PLS regression of design parameters on MRI parameters. The inner and outer circles indicate 50 and 100% explained variance in the model, respectively. The first factor explains 26% of the total variance of the design variables (X), which models 32% of the variance in the measured NMR parameters (Y). Factor 2 explains 25% of the variance in the design variables modeling 6% of the Y variance. The X loadings show that salting time, fish part and fish size govern most the variation both in the first and second factor whereas, acquisition position (slice) has almost no effect. The Y loadings reveal that high salt content in the smoked salmon was positively correlated both to long salting time and fish part and negatively correlated to the fish size. The posterior part had higher salt content than the anterior part and small fish were saltier than large fish. Salting time and part, which explained more than 50% of the variance in the model, used, had the largest effects. Similar results are previously reported based on ^{23}Na and ^{35}Cl SQ of smoked salmon [12]. The different salt content in the anterior and posterior part of the fish was explained by a greater penetration of salt in the thin part than in the thick part. Due to the simultaneous acquisition of ^{1}H and ^{23}Na imaging, which allows us to directly compare fat and Na content in each sample, our results reveal that the fat content may also has an effect on the obtained salt content (Figure 4). In Figure 5 it looks like that the fat content is negatively correlated to the Na content. However, the fat content is both related to the fish size and the part, but since only 6% of Y is explained by Factor 2 we may assume that the fat content is almost independent of the fish size. Thus we may conclude that there is not only an effect of fish part and size (fillet thickness) on the salt content, but that the fat content of the fish has an effect on the obtained salt content as well. The effect of the higher fat content may be that it hinders the salt diffusion through reducing the water mobility. In this experiment the variation in the T_2 values were in general small and no clear conclusion should be drawn with regard to this parameter. However, the correlation plot of Factor 1 vs. Factor 3 (not shown) revealed that the T_2 and fat content was opposite correlated along Factor 3, but the explained variation of this factor was small. T_2 was also negatively correlated to the sodium content.

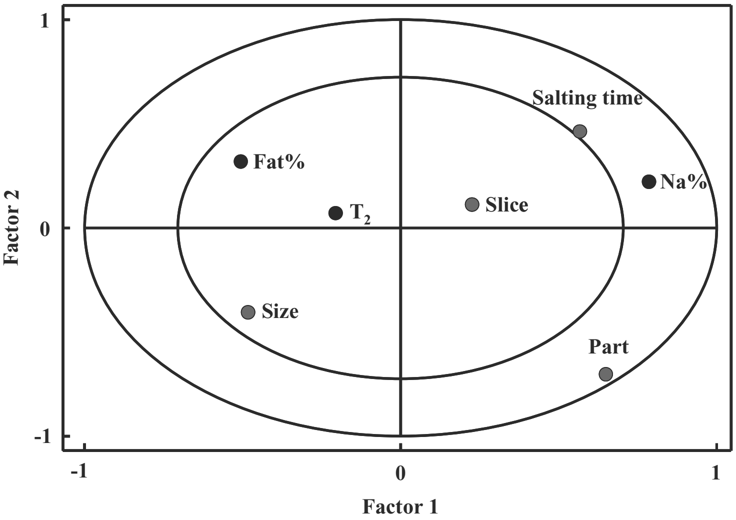

Fig. 5. Factor 2 versus factor 1 correlation X- and Y-loadings from a PLS regression of design variables on MRI parameters. The X-loadings (grey) are labelled according to fish size (large = 1, small = 0), Salting time (short = 0, long = 1), Part (posterior = 0, anterior = 1) and Slice (acquisition position) valued 0–3, from the ventral to the dorsal side of the fillet section. The Y-loadings (dark) are labelled Fat%, Na% and T_2 for the normalised mean values recorded from the images.

Conclusion

The different ^{1}H, ^{23}Na, and ^{35}Cl MRS or/and MRI protocols described here emphasize the wealth of information that can be accessed for the characterization of salting process and their discrimination.

Preface

It is a great pleasure for me to Introduce the handbook of Modern Magnetic Resonance, MMR. The various techniques which comprise MMR derive essentially from three sources, all of which were produced by physicists. Today they are widely used by scientists working in many diverse areas such as chemistry, biology, materials, food, medicine and healthcare, pharmacy and marine studies.

The first source of MMR studies is nuclear magnetic resonance, NMR. This provides details on the relative positions of nuclei, i.e. atoms, in a molecule. Consequently NMR provides structural information on samples which may be in the solid, liquid or gaseous state. Nuclear relaxation data yield dynamic information on the sample and the topology of the dynamic processes if the sample is undergoing a molecular change. Thus high and low resolution NMR studies provide information on all interesting aspects of molecular science. The protean nature of NMR is reflected in its many applications in chemistry, biology and physics which explore and characterize chemical reactions, molecular conformations, biochemical pathways and solid state materials, to name a few examples.

Magnetic resonance imaging, MRI, is the second source of MMR data. MRI provides a three-dimensional image of a substance, and is consequently widely employed to assess materials both *in vitro* and *in vivo*. The importance of MRI studies in many areas of science and medicine is shown by the recent award of the Nobel Prize to Lauterbur and Mansfield.

The third source of MMR results is due to electron spin resonance, ESR. This is a technique for detecting unpaired electrons and their interactions with nuclear spins in a given sample. Thus ESR data are often used to complement the results of NMR experiments.

Taken together NMR, MRI and ESR comprise the field of MMR, recent years have witnessed the fecundity of these techniques in many scientific areas. The present three volumes cover applications in most of these areas. Part 1 deals with Chemical Applications, Biological and Marine Sciences. Medical and Pharmaceutical Sciences are covered in Part 2. Part 3 provides examples of recent work in the Materials Science and Food Science.

I wish to express my gratitude to all of the Section Editors and their many contributors for their hard work and dedication in the creation of MMR. My thanks also go to Emma Roberts and the production staff at Springer, London, for their assistance in the realization of these volumes.

Part II, Section 1:
Applications in Medical Science

Foreword to Applications in Medical Science

Magnetic resonance (MR) remains an emerging trend in technological innovation. In support is the award of four Nobel Prizes since 1991. Magnetic resonance has provided a paradigm shift in medical diagnosis and treatment planning and now plays an ever increasing role in health and medical research. Magnetic resonance imaging (MRI) is used worldwide with magnetic resonance spectroscopy (MRS), functional MRI and intraoperative MRI increasingly used in the clinic and for medical research purposes.

Each is technically difficult and requires a determined effort by those who develop, and use, the methods to obtain reproducible output at multiple sites. In the case of medical applications multidisciplinary teams are needed to develop, test and implement the method for routine clinical use in a controlled environment.

In this volume the authors, researchers from around the globe, have documented their technology in a way that will allow others to implement the methods for either research or clinical use. They share their many years of experience with the readers. We would like to thank them for taking the time to write their contributions with the end-user in mind.

We hope that the field of magnetic resonance in medicine will benefit from this volume by sharing the various experimental protocols and details. This will ultimately translate into improved medical care.

We would like to thank Professors Robert Lenkinski, Brian Tress, Drs Roger Bourne, Peter Malycha, Alan McLaughlin, Saadallah Ramadan, Robert Savoy and Peter Stanwell for their assistance reviewing the chapters.

Our special thanks to Dr Deborah Edward for the large amount of time and effort she put into editing and collating the Chapters. Thanks also to Sinead Doran for assistance with the diagrams.

Carolyn Mountford D. Phil (Oxon)
Uwe Himmelreich Ph.D.

W-F: water-to-fat ratio

WM: white matter

Metabolite Abbreviations

Ala: Alanine

ATP: Adenosine Triphosphate

Cho: Choline

Cr: Creatine

Eth: Ethanolamine

Glx: Glutamine/Glutamate

GPC: Glycerophosphocholine

GPE: Glycerophosphoethanolamine

Lac: Lactate

MI: Myo-Inositol

NAA: N-acetyl aspartate

NTP: Nucleotide Triphosphate (e.g., ATP)

PC: Phosphocholine

PCr: Phosphocreatine

PE: Phosphoethanolamine

Pi: Inorganic Phosphate

SI: Scyllo-Inositol

Tau: Taurine

UDP: Uridine Diphosphate

Glossary of Terms

Abscess: Focal infection that consists of an abscess capsule, containing fibrous material and chronic inflammation cells, and a central cavity filled with pus.

Absolute quantitation: Determination of concentrations of metabolites in mMoles per kg of tissue or volume.

Astrocytoma: The most common type of brain tumor in adults; astrocytomas, known for their marked potential for malignant progression and infiltrative nature, can be classified histopathologically into three grade of malignancy: WHO grade II astrocytoma, WHO grade III anaplastic astrocytoma, and WHO grade IV GBM.

B_0: Strong magnetic field, constant in time and space, generated by the superconducting magnet.

B_1: Radiofrequency (RF) magnetic field generated by *radiofrequency coils*.

Benign Prostatic Hyperplasia: Enlargement of the prostate and more specifically, overgrowth of the epithelium and fibromuscular tissue of the transition zone and periurethral area.

Bifunctional contrast agent: Contrast agent that increases the intrinsic contrast for two different imaging modalities.

calar coupling: See *J-coupling*

Contrast agent : Chemical compound that increases the intrinsic contrast in an image.

Δf: bandwidth (in Herz) of the receiver

Dendrimers: Large and complex polymers of a consistent size and a regular and highly branched architecture. They are often used for the encapsulation of smaller molecules.

Ductal Carcinoma In Situ: Noninfiltrative lesions composed of malignant epithelial cells that are confined to the mammary ducts and lobules.

Endocytosis : In endocytosis, the cell engulfs some of its extracellular medium including material dissolved or suspended in it. A portion of the plasma membrane is invaginated and pinched off forming a membrane-bound vesicle called an endosome.

Endosome : Vesicle formed during endocytosis.

η: filling factor

F: noise figure of the preamplifier

Focal infection: Infection that is results in the formation of lesions. Can be caused by bacteria, fungi, parasites or viruses.

Glioblastoma Multiforme: Highly malignant tumour with a low overall survival time for most patients. They are histologically characterised by a dense cellularity, high endothelial proliferation, and often the presence of focal tissue necrosis. These tumours are can occur in a cystic form.

Glioblastoma Multiforme: The most malignant grade of astrocytoma (WHO grade IV), which has an overall survival time of less than two years for most patients. These tumors are histopathologically characterized according to their dense cellularity, high proliferative indices, endothelial proliferation, and most importantly the presence of focal tissue necrosis.

Hetero-nuclear J-coupling: *J-coupling* between different species of spins, e.g. proton and carbon.

Homo-nuclear J-coupling: *J-coupling* between the same species of spins, e.g. proton and proton.

ISIS: **I**mage-**s**elected ***in vivo*** **s**pectroscopy is based on a cycle of eight acquisitions which need to be added and subtracted in the right order to get a single volume. ISIS is considerably more susceptible to motion then *STEAM* or *PRESS* and is mostly used in heteronuclear studies, where its advantage of avoiding *T2-relaxation* is valuable.

J-coupling (or scalar coupling): Many resonances split into multiplet components. This is the result of an internal indirect interaction of two spins via the intervening electron structure of the molecule. The coupling strength is measured in Hertz (Hz) rather than *ppm* because it is independent of the external B_0 field strength.

k: Boltzman constant

K: numerical factor depending on the coil geometry

Lipoma: Commonly diagnosed benign tumors of adipose tissue that can develop anywhere in the body where fat is normally found.

Liposarcoma: A commonly diagnosed soft tissue sarcoma in adults which be found anywhere in the body and for which there exists several types with varying clinical outcomes.

Meningioma: Intracranial tumors that arise in the meninges and compress the underlying brain. In general, many of these tumors are benign, however, others are malignant with the capability to metastasize, both locally and distally.

Metabolite Profiling: The study of small molecules, such as lipids, peptides, amino acids and carbohydrates, which represent steady state concentrations of intermediate products or end products of cellular processes and as a result can be thought of as the ultimate response to genetic and environmental stimuli.

Mo: Magnetization

μo: Permeability of free space

Molecular imaging: Non-invasive, *in vivo* visualization of cellular and molecular events in normal and pathological processes.

Necrosis: Tissue and/or cell death.

Neoplasm: Literally meaning "new growth". An abnormal growth of tissue which may be benign or malignant.

NOE: Nuclear Overhauser effect, the magnetization of protons dipolar-coupled to ^{13}C nuclei can be used to enhance the ^{13}C signal. While the term NOE is mainly associated with ^{13}C MRS, NOE enhancement can also be observed in ^{31}P MRS and with other nuclei.

ω0**:** Larmor frequency

Oncogenomics: The study of genes, gene sequences, and the underlying genetic alterations that appear to be involved in oncological pathways.

Polarization transfer: Many interesting nuclei like ^{13}C suffer from low inherent sensitivity compared with proton MR. Techniques like DEPT (**d**istortionless **e**nhancement by **p**olarization **t**ransfer) and INEPT (**i**nsensitive **n**uclei **e**nhanced by **p**olarization **t**ransfer) improve the ^{13}C sensitivity by transferring the higher polarization of coupled protons to the carbon nuclei. Special hardware with two RF channels is needed for polarization transfer experiments. A modification of DEPT and INEPT is reverse DEPT and inverse INEPT where the polarization is transfered back to utilize the higher sensitivity of the protons for observation (inverse detection).

PRESS: Point-resolved spectroscopy, utilizes three 180° slice selective pulses along each of the spatial directions and generates signals from the overlap in form of a spinecho.

Pus: Content of an infective lesion. It consists of dead and dying polymorphous cells (leucocytes), living and dead microorganisms, tissue debris and other components of inflammation (oedema fluid and fibrin).

Q: Quality factor of the coil

Reactive Nodes: Lymph nodes that have been immunologically challenged.

Responsive contrast agent: Contrast agent that conditionally increases the intrinsic contrast (depending on the change of environmental conditions like enzyme activation, pH change, change in ion concentration and others).

SAR: Specific absorption rate. Due to inductive and dielectric losses energy from radiofrequency pulses is absorbed by tissue and mainly transferred into rotational and translational movements of water molecules which causes an increase of tissue temperature. Limits for the human brain are established by FDA guidelines.

Schwannoma: Benign tumors that arise on peripheral nerves in general and on cranial nerves in particular, especially on the vestibular portion of the eighth cranial nerve.

Sensitivity: The term relating to the percentage of people with disease who test positive for the disease, i.e. the percentage of patients with cancer who have positive biopsy results.

SNR: Signal to noise ratio

Specificity: The term referring to the percentage of people without disease who test negative for the disease, i.e. patients without cancer with cancer negative biopsy results.

STEAM: Stimulated **e**cho **a**cquisition **m**ode, localization method utilizing three 90° slice selective pulses, along each of the spatial directions. Signal, in form of a *stimulated echo*, from the overlap is generated in a "single shot" experiment. In contrast to *PRESS*, only half of the possible signal is recovered when the same *echo time* is used.

Stem cell: Cell with broad differentiation potential that retains the capacity for unlimited self-renewal. A totipotent stem cell has the ability to differentiate to all cell types of an organism, whereas a pluripotent stem cell produces many but not all cell types.

T1-relaxation, T1-relaxation time: After the *magnetization* vector has been flipped into the transverse plane, new magnetization builds up along the z-axis. The time after 63% (1-1/e) of the equilibrium magnetization has built up is called the T1-relaxation time. T1 and T2 relaxation is caused by time-dependent fluctuations of local magnetic fields arising mostly from the motion of molecules with electric or magnetic dipoles at the site of the spins. For accurate *absolute quantitation* the relaxation times of all metabolites must be known in order to correct peak intensities appropriately.

T1-saturation: The repetition times *TR* are usually in the range of the *T1-relaxation* times. As a consequence of this, not all the *magnetization* has recovered, for example when TR = T1 only 63% of the equilibrium magnetization can be used for each scan (with the exception of the first scan) when 90° flip angles are used for excitation. This effect is called T1-saturation. The extreme case of saturation occurs when several *RF pulses* are applied within a very short time followed by dephasing *gradients*. This technique is used in localized ^{1}H MRS to remove the dominant water signal (see *water suppression*).

T2-relaxation, T2-relaxation time: The *magnetization* vector can be flipped into the transverse plane by using an *RF pulse*. The so generated transverse magnetization undergoes an exponential decay. The time after the magnetization has relaxed to 37% (1/e) of its amplitude is called the T2 or transverse or spin-spin relaxation time. See also *T1- relaxation*

.

Tc: probe temperature

TR (repetition time): The time between each initial excitation of the magnetization is called the repetition time.

Transfection: A method by which experimental DNA (or in our case contrast agents) can be incorporated into mammalian cells after interaction of the encapsulating transfection agent and the cell membrane.

Vc: volume of the coil

Acquiring Neurospectroscopy in Clinical Practice

Alexander P. Lin

Huntington Medical Research Institutes, Rudi Schulte Research Institute, Pasadena, CA 91105, USA

Part I: Seven Secrets to Successful Spectroscopy

Neurospectroscopy or magnetic resonance spectroscopy (MRS) has moved from the realm of academic research into that of the clinical world. All major MR manufacturers have aided in the endeavor by automating neurospectroscopy so that it no longer requires an MR physicist and is a push-button technique that can be run by technologists just as a typical MR sequence. Thousands of papers have demonstrated the clinical efficacy of neurospectroscopy and there are a dozens of medical reviews of how this technique can be applied across a wide range of neurological disorders. However, few papers address the practical issue of acquiring neurospectroscopy in a clinical practice. Based on over a decade of clinical experience on our 1.5 T scanner and applications training for technologists and radiologists at our international clinical neurospectroscopy courses, this chapter was developed to demonstrate proven protocols for clinical diagnosis and outline the strategies involved in acquiring successful clinical spectra.

Introduction

While the goals of the MR technologist are not very different between imaging and spectroscopy, the terminology and approach are slightly different. Imagers desire clear and detailed images without motion artifacts. Spectroscopists want spectra with well-defined peaks and few artifacts as well. The composition of a peak can be broken down to two parameters: (1) peak height or how readily discernible the metabolites are from noise; this in turn is governed by the principles of signal-to-noise ratio (SNR) and (2) line width or how narrow the peaks are, which is governed by magnetic field homogeneity. It is the goal of the spectroscopist to therefore maximize these two principles using a variety of different parameters discussed in this chapter. Using the same analogy, imagers use different sequences such as T_2w or FLAIR to investigate certain pathological properties; spectroscopists use different protocols to diagnose different disorders. These protocols can be broadly categorized into focal and global protocols, each of which will require a different approach to these parameters.

When we began developing and growing a clinical spectroscopy program, we soon discovered that the "secret" to a successful spectroscopy service was CONSISTENCY. Once a methodology of acquisition or guideline is established, it must be maintained. In any clinical MR unit, all technologists must follow that guideline in order to guarantee spectral reliability from patient to patient. Worldwide, the same consistency is essential to ensure "universality" of clinical diagnosis.

Signal and Homogeneity

In the following sections, we will be discussing different parameters that can be changed to optimize your spectroscopy. There are two components to optimization, namely: SNR and homogeneity. With a high SNR, the metabolite peaks (signal) are very easy to distinguish from the smaller peaks that surround it (noise) as you can see in Figure 1. High SNR is critical to the interpretability of spectra by both the radiologist and the automated processing software. Maintaining high SNR throughout all your acquisitions is a prime responsibility for spectroscopy quality control. The factors that affect SNR are (in order of impact): voxel size, number of averages, echo time (T_E), localization sequence, and repetition time (T_R).

Homogeneity refers to the uniformity of the magnetic field present in the voxel of interest (VOI: a voxel is the box which defines the area you wish to examine). A very homogeneous field has very little change in the magnetic field throughout the VOI (Figure 2B). A heterogeneous field has differing magnetic properties throughout the VOI (Figure 2A). A "sharp" spectrum at 1.5 T reflects both consistent and relatively thin line widths (<3 Hz) as shown in Figure 2D. The reason why spectroscopy is performed primarily in the brain is that the magnetic field is remarkably homogeneous throughout it. A severe example of inhomogeniety would be the magnetic field as dental braces affect it. By having a homogeneous field in your VOI, you reduce the chances of artifacts that would make the spectrum unreadable. These artifacts can affect the entire spectrum or affect just a certain area of chemical shift, however, you would like to avoid them if at all possible. The elements that cause homogeneity problems will be discussed in voxel positioning.

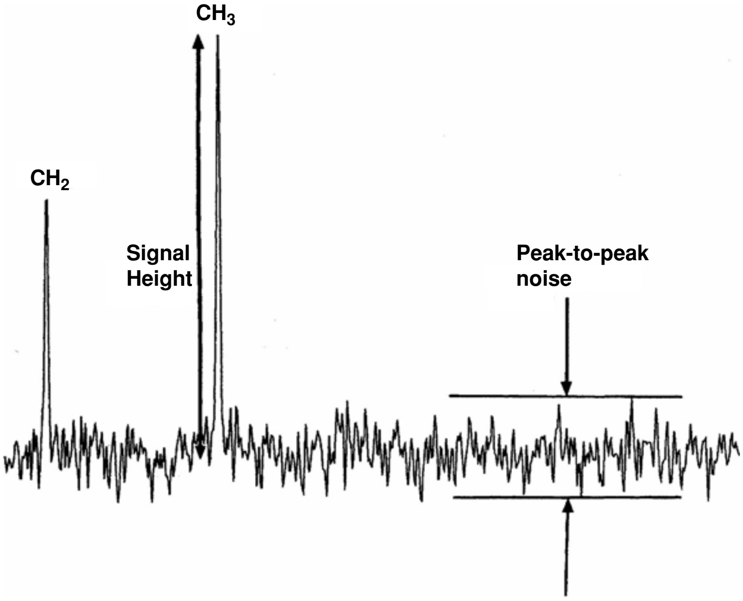

Fig. 1. Definition of signal-to-noise ratio. The large peak labeled as CH_3 is the signal and the peak-to-peak noise is indicated. Signal-to-noise ratio is simply the dividend of the height of the two measurements.

Acquisition Paradigms

As you will see throughout this chapter, there are essentially two methods of acquiring spectra: FOCAL vs. GLOBAL. The definition in terms of spectroscopic applications is as follows:

- *Focal:* Acquiring spectra from specific regions of interest that are variable from patient to patient. For example: in brain tumor spectroscopy, the location, size, and homogeneity of the tumor will differ from patient to patient. It is therefore critical to understand the underlying concepts behind each parameter such that you can use it to your advantage in different situations.
- *Global:* Acquiring spectra from a specific region of interest that is the same in all patients. A well-defined protocol is used for this type of spectroscopy. For example, in diagnosing Alzheimer's disease, the technologist will always place the voxel in the posterior cingulate gyrus (PCG) in the posterior parietal lobe of the brain. In this paradigm, very little changes from patient to patient. Therefore, great care must be taken to ensure that the protocol is followed to the letter.

Patient Positioning

Patient positioning plays a key role in maintaining consistency from patient to patient as well as from exam to exam. This is critical in use of spectroscopy for monitoring treatment or determining medication efficacy. More and more clinicians are turning to spectroscopy as a noninvasive tool to help determine how the patient is progressing in a quantitative way through neurospectroscopy. If the patient's head is not in the same position from his/her first MRS exam before treatment, it makes it all the more difficult to compare the results of the MRS exam after treatment.

- Landmark the patient at a consistent anatomical location. The eyebrow is a good location that is easily determined in each patient (Figure 3). By routinely landmarking in the same location, you can ensure that you are achieving maximum homogeneity within the magnet bore.
- Make sure the patient's head is centered. The left and right halves of the patient head should be symmetrical. This is critical for exams that compare the contralateral areas of the brain.
- Try to place the center of the coil at the landmark position. This ensures that the most homogeneous part of the coil is at the area of the brain where you will be acquiring your spectra. Depending on the anatomy of the patient, this may be difficult (i.e. short neck); however, try to do your best!
- Reduce patient movement by securing the head. Foam inserts or rolled up towels to the left and right side of the head help to reduce the chance of the patient moving their head after imaging (Figure 3). Using a strap around the forehead can also be useful but difficult to employ in claustrophobic patients.

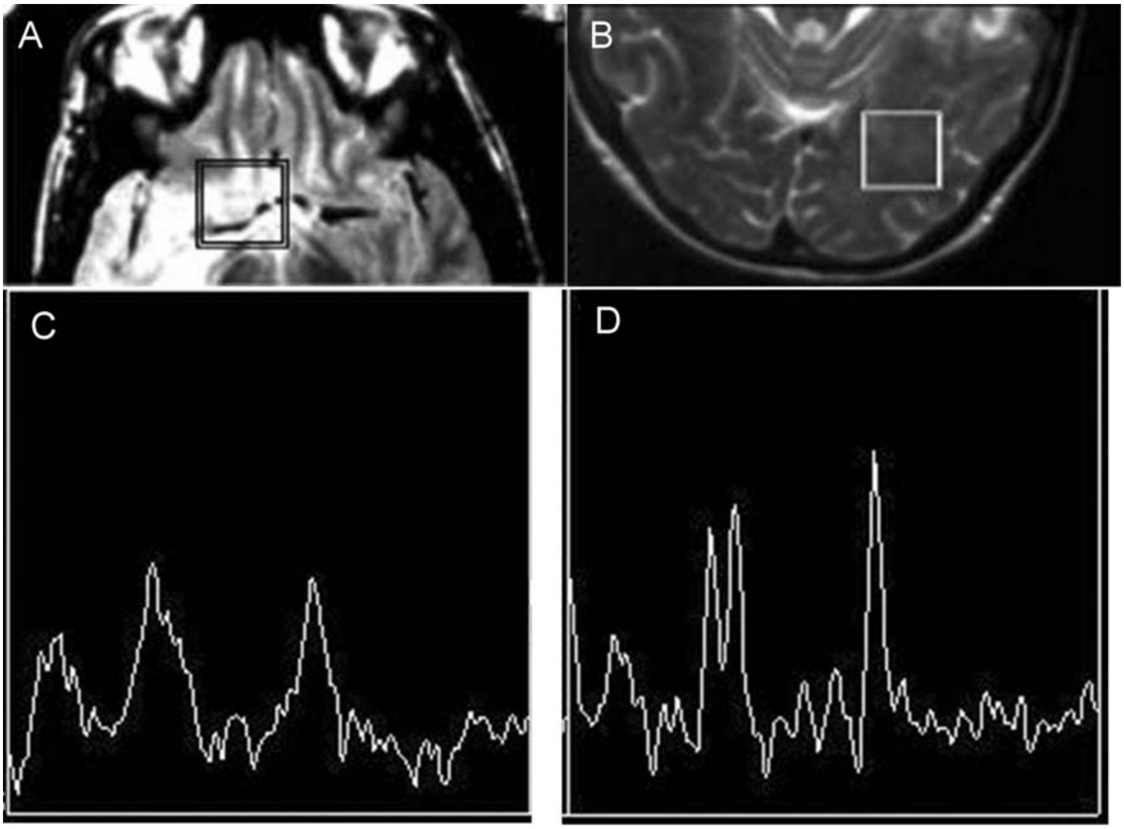

Fig. 2. Example of poor and good homogeneity. (A) This MRI image on the left demonstrates a voxel (indicated by the square) that contains different types of tissue as well as arteries. This is a very heterogeneous region. (B) The image on the right contains a voxel (square) from a very homogeneous region. (C) The long echo spectrum that was the result of the heterogeneous voxel in image A on the left has low signal as well as poor homogeneity as evidenced by the lack of splitting between Cho and Cr. (D) The long echo spectrum on the right, the result of the homogeneous voxel indicated in image B, although not of excellent quality, has enough signal to be interpreted.

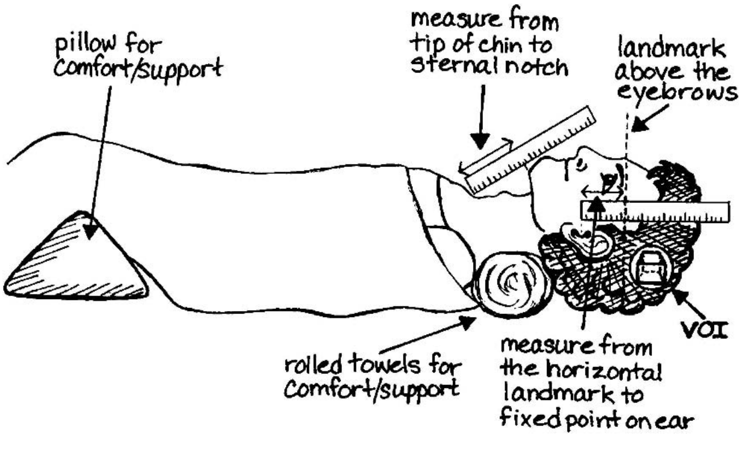

pillow for Comfort/support

measure from the horizontal landmark to fixed point on ear

Fig. 3. Good positioning is achieved by a proper landmark, increased patient comfort, and additional measurements that can be used for repeat exams. Pillows and rolled towels provide comfort and support that prevents the patient from squirming about. Measurements such as those shown can dramatically improve spectral reproducibility.

Sequences

Manufacturers have greatly improved upon the localization sequences used in diagnostic spectroscopy. PRESS can reliably acquire spectra at short echo times and gives an almost doubled SNR advantage over STEAM. It is clearly the localization sequence of choice.

However, in many of the protocols described in available clinical texts, STEAM localization was utilized to acquire the spectra at 1.5 T. It is important to note that there are significant differences between metabolite ratio values for STEAM and PRESS that go beyond a simple scalar increase in SNR. For example, in exactly the same voxel in the same patient STEAM will give an NAA/Cr of 1.35, whereas PRESS will give a value of 1.71! Therefore, in order to use the spectra presented in other textbooks and papers as a comparison, you MUST use the exact methods described in the protocol. To avoid errors in diagnosis and in order to compare against those results, it is imperative not to mix STEAM and PRESS sequences. It is best to rigorously adhere to ONE sequence.

Echo Time

The greatest advantage of short echo neurospectroscopy is that the shorter the echo time, the greater the signal. Of course there is a practical limit to how short an echo time can be acquired. In general, echo times of 21–35 ms are used for neurospectroscopy. Another advantage of short echo times is that metabolites with short T_2 relaxation times such as *myo*-inositol, glutamate, glutamine, *scyllo*-inositol, etc. can be observed as shown in Figure 4. This adds to the diagnostic power of neurospectroscopy. For example, the diagnosis of Alzheimer's disease is less sensitive with NAA alone; the addition of mI allows neurospectroscopy to achieve excellent sensitivity and specificity. Initially, short echo neurospectroscopy was more prone to artifacts, however, at this time PRESS is robust. Because of another property of brain metabolites, termed *J* coupling, even small differences in T_E are critical: while using 27 ms may not give significantly different results, using 45 ms will!

So why use long echo time ($T_E = 135$, 144, 270, 288 ms)? Initially, it reduced the baseline "artifacts" observed sometimes with short echo spectroscopy. Also at long echo, lipid signals are significantly reduced, allowing other metabolites to be observed originally obscured by lipid. At $T_E = 135$ or 144 ms, lactate is easily observed as an inverted doublet (an admirable use of *J* coupling as described above), whereas in short echo it can often be hidden within the lipid resonance. This is all at the sacrifice of SNR of at least 40% as well as the reduction in the number of diagnostic markers. Typically, echo times of 135 or 144 ms are used. If you do decide to employ long echo times, be sure to recognize that the normal spectra heights are dramatically different in long echo than they are in short echo simply due to different intrinsic metabolite T_2 relaxation times. It is therefore imperative to stick with just ONE choice of echo time to save yourself from confusion and misdiagnosis.

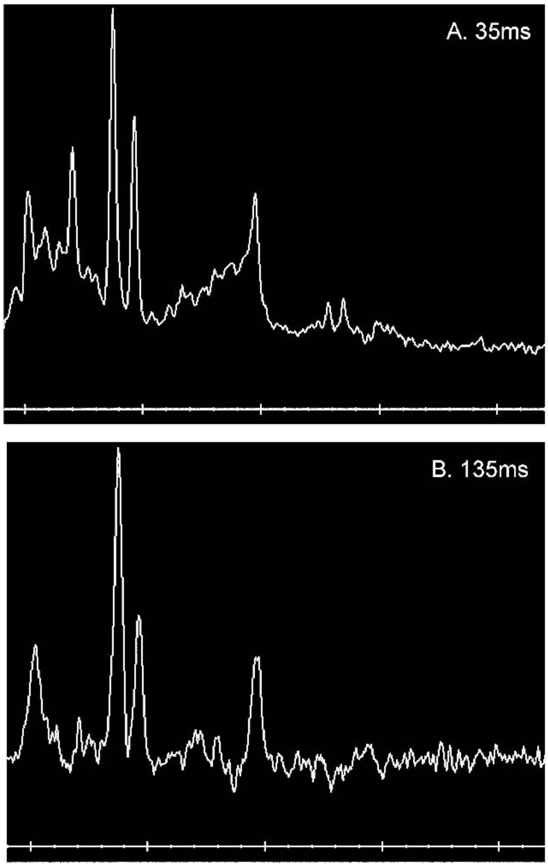

Fig. 4. Both of these spectra were acquired from the same exam using the same voxel position, voxel size, and number of averages using PRESS in a patient with recurrent brain tumor. The spectrum on top was acquired with an echo time of 35 ms, the bottom spectrum at 135 ms. Note that the Cho/Cr is vastly different and mI is absent in the bottom spectrum. Although the abnormal choline that is diagnostic of brain tumor is evident in both spectra, additional information, such as the significantly elevated mI that may indicate low-grade glioma, is missing from the long echo spectrum. It is difficult to tell the amount of signal loss since both spectra are scaled to the highest peak. However, the noise is much greater at long echo when compared to short echo to the extent that the small amount of lactate, which is diagnostic in the short echo spectrum, is not observed in the long echo spectrum.

Voxel Size

SNR is highly dependent on your voxel size. The typical voxel size of 2.0 × 2.0 × 2.0 cm (8 cc) is standard on most 1.5 T scanners. This is also an optimal voxel size for most 1.5 T applications (except notably in neonatal neurospectroscopy where smaller voxels may be required). In global diseases, the voxel sizes are well established and should not change from patient to patient. In some protocols, the default of 8 cc may not be used due to location-specific optimization; nonetheless, all patients examined with that particular protocol must have the same voxel size.

However, with focal neurospectroscopy, 8 cc may not be suitable to obtain enough partial volume of the lesion or may be too small for a large lesion. For lesions that are smaller than 8 cc, we recommend that you first obtain a spectrum from the larger volume to guarantee that you receive signal at all. A common mistake is to shrink your voxel to too small a volume as shown in Figure 5. In that case, there will not be enough signal to generate a readable spectrum. If the first voxel is successful, then at the very least the radiologist has some data to review. For a more accurate reflection of the metabolites within the lesion, after obtaining a successful first voxel, one can

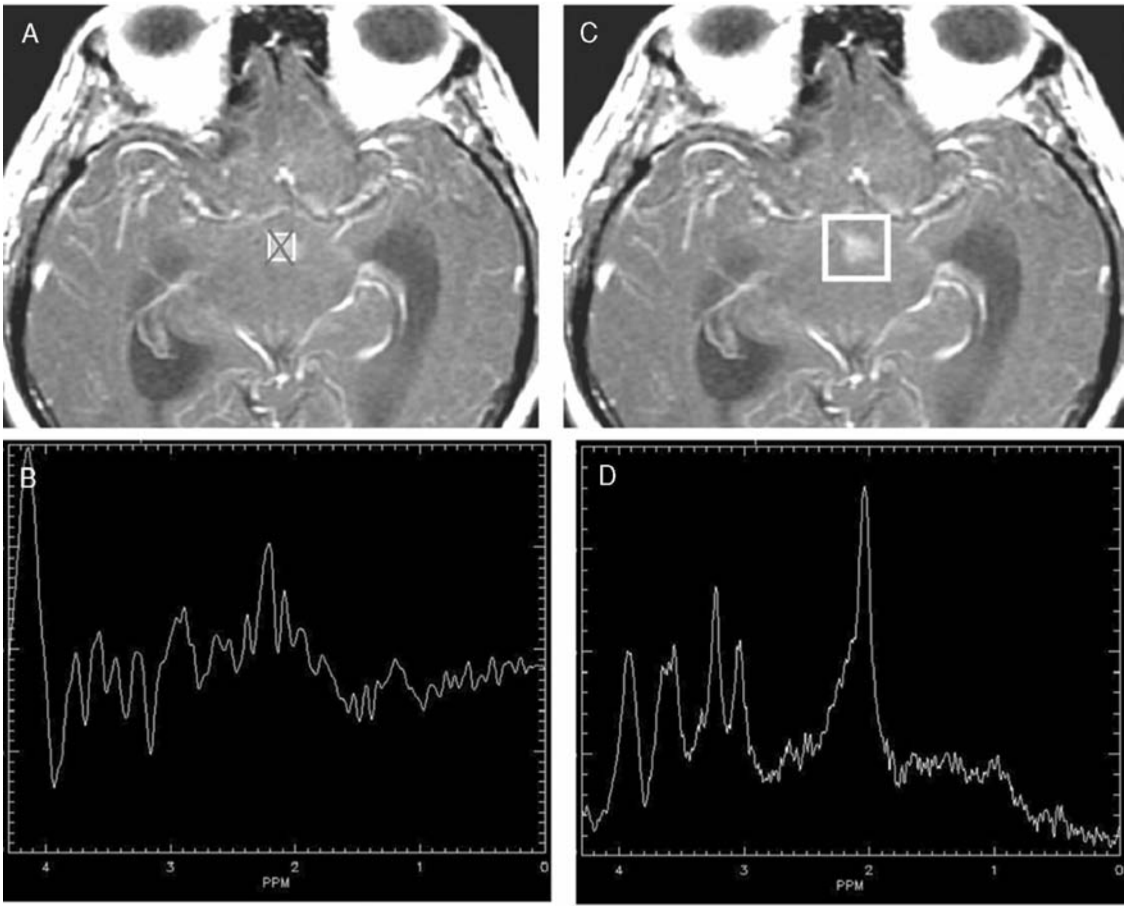

Fig. 5. Example of how voxel size affects spectral quality. In this patient case, a small hyperintense signal was discovered in the MRI that was too dangerous for surgical biopsy. Furthermore, MRI was indeterminate for neoplasm or stroke. It is therefore imperative for neurospectroscopy to provide an answer. When trying to acquire signal from a small lesion, it is common to try to shrink the voxel size to as small as possible. The result of such a small voxel (A) results in an uninterpretable spectrum (B). Although the larger voxel (C) has a small partial volume of the lesion, it produces (D) a good quality spectrum that gives a diagnostic result (high Cho) that proved to be a brain tumor.

then shrink the voxel to increase the partial volume. A good rule of thumb is that if the lesion occupies greater than 40% partial volume, there will be enough signal from tumor to generate an abnormal spectrum.

If the lesion is greater than 8 cc, then it would most likely make more sense to increase your voxel to match that volume. However, the larger the voxel, the greater the chances of observing inhomogeneity effects (such as artifacts and eddy current problems) in the volume. We recommend not obtaining a voxel larger than 30 cc. It is best to use a volume between 8 and 27 cc and change the voxel position instead of trying a larger voxel. This will be further discussed in the section regarding voxel position.

Another option when dealing with partial volume is to not assume that the voxel volume must be cubic. The advantages of using a different shape would be to maximize partial volume or minimizing the artifacts that one may get. For example, in trying to obtain a spectrum from the basal ganglia, we have observed that by using a rectangular voxel shape one can obtain a greater partial volume of the basal ganglia as well as minimizing the chances of the voxel being affected by other structures, such as the ventricles. However, it is best to keep the shape of the voxel as close to a square as possible since manufacturers most likely optimized their hardware to a cubic volume.

Number of Averages

The number of averages is directly proportional to SNR. This implies that the longer the acquisition, the more signal one can get. Obviously there are limits to the amount of time one can spend for each voxel. This is dependent not only on the patient's limits of tolerance but also due to the number of acquisitions required in a certain protocol. The total time for the scan is the prescan plus the number of averages in the scan multiplied by the repetition time.

In the global paradigm where you already have a defined size and location, it is best to set the number of averages the same for every acquisition as it does not need to be adjusted for signal and homogeneity effects. The data from the defined size and location should also always be acquired with the same number of averages.

In the focal paradigm, adjustments are dependent on the size of the voxel. Generally an 8 cc voxel requires 128 averages for a high quality spectrum. If you reduce the volume to half, you must increase the number of averages to 256 in order to maintain the same spectral quality. Therefore, if you use a very small volume such as 2 cc, you would require 512 averages, which at $T_R = 1.5$ ms would take nearly 13 min! This implies that small volumes are NOT the place to start acquiring data, hence why we recommend first acquiring data from an 8 cc volume and then reduce size accordingly. Homogeneity within the voxel should also factor into your determination of number of averages. By averaging for longer time, you reduce the artifacts that can occur in a heterogeneous acquisition.

Voxel Position

Voxel position is an inherent part of optimizing your ability to collect interpretable spectra. More importantly, the position plays a key role in the diagnostic power of the spectra. The diagnosis of diseases with neurospectroscopy is dependent on differences in metabolite peak heights as compared to normal values. If the difference you observe in a certain pathology is 15%, the reproducibility of that voxel must be 10% or better. In order to optimize reproducibility, the voxel parameters must be the same in every patient. All other parameters can be set as part of a protocol, leaving voxel position as the only factor that can affect reproducibility.

For example, in the diagnosis of Alzheimer's disease, an increase of mI/Cr of 10% is considered "significant." How does one determine if this change is significant? Utilize the standard deviation in a cohort of spectra from normal, healthy adults. In this case, the standard deviation is 5%; therefore the physician can rightly assume that the 10% change in mI/Cr is due to pathology and not due to normal variation in the human brain. In order to ensure that the standard deviation in all measurements was 5%, one must maintain reproducibility of the spectra. The voxel is placed and landmarked in the same position in every patient. The greater the reproducibility of the voxel, the less likely that the change observed has come from a different voxel location.

As with voxel size, changing voxel position can greatly alter your results when dealing with global spectroscopy. Gray and white matters contain different Cho/Cr ratios, therefore a shift in voxel position, causing it to contain more white than gray matter could lead the reader of the spectra to believe that there is a higher Cho/Cr in the voxel that he/she will attribute to pathology. This is the wrong conclusion to draw if the voxel position is incorrect and the observed change is due to greater partial volume of white matter. Although not all brains are exactly the same, using anatomical landmarks, such as the ventricles, will allow for a high measure of reproducibility. Positions for each diagnostic test will be described in detail with accompanying figures in the following section.

When dealing with the focal spectroscopy paradigm, the concerns of acquiring exact voxel position from patient to patient is disregarded because by definition, the key location will NOT be the same from patient to patient. In this case, it is more important to optimize the position such that you increase homogeneity as well as

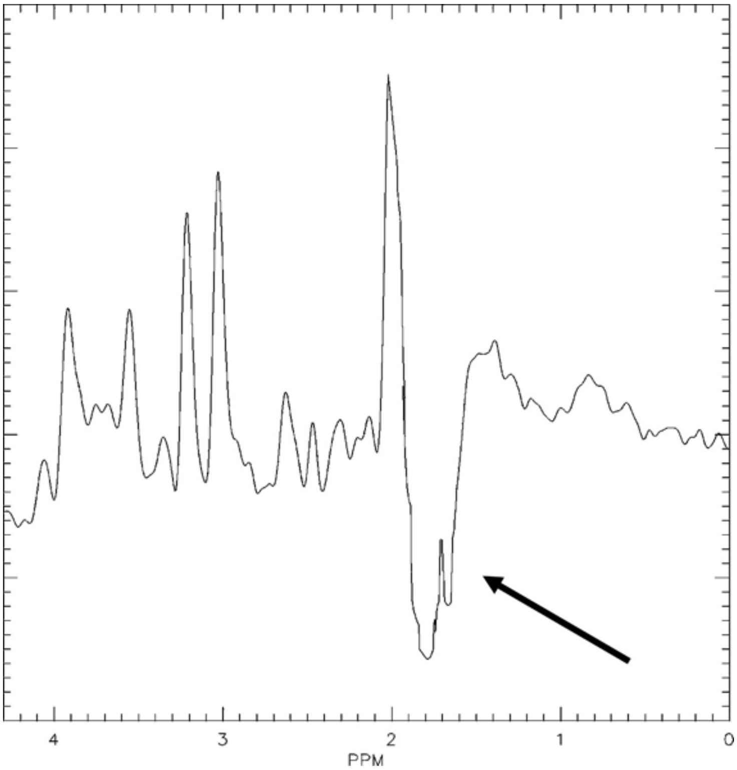

Fig. 6. Example of out-of-volume lipid artifact. The artifact is indicated by the arrow. This artifact comes about as a result of the voxel being to close to the back of the brain. The danger of this artifact is that it may impact upon the NAA signal that results in an artificially low NAA/Cr reading that would impact on spectral interpretation. This artifact is the reason why with voxel placements described in Protocols 1, 2, and 3 in Part II of this text it is critical to stay away from the skull.

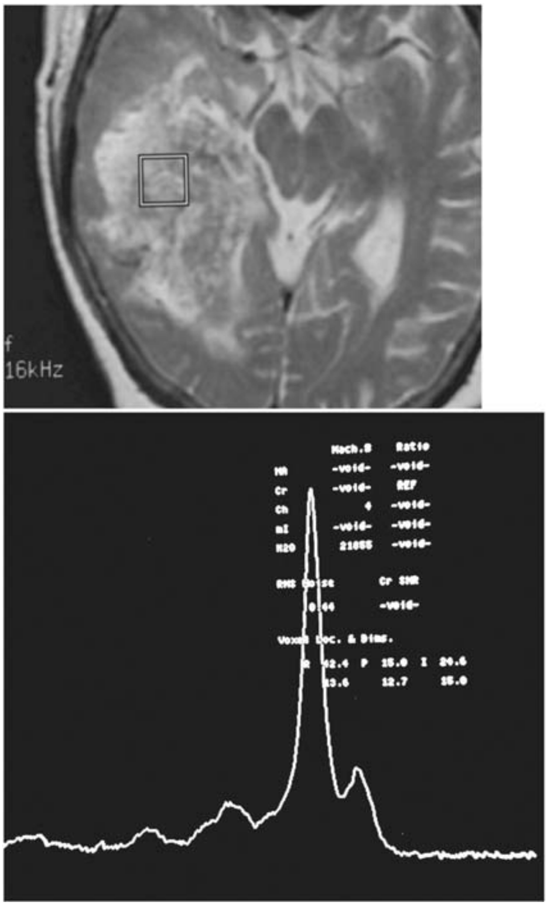
signal. While in each pathology, different techniques in determining voxel position can be used; there are some areas of the brain or pathology you want to avoid:

- *Skull:* Stay away from the surfaces of the brain. The lipids that lie in the meninges of the brain, within the bones of the skull, or in the scalp can contaminate your spectra in two ways: (1) By creating an overriding lipid signal that can be misinterpreted or can dominate the entire spectra thus hiding the spectra; (2) an artifact that can result is "out-of-volume lipid artifact" (Figure 6) which is a large broad negative resonance or "dip" in the spectra around 1.8 ppm which can cause the resonance for NAA that resides at 2.0 ppm to be "dragged" down. Be sure to check all slices of the image that your voxel is located to ensure you have not come too close to the skull.
- *Necrosis:* As described above, lipids can cause severe problems with spectra. One major problem is domination of the spectra as shown in Figure 7. The spectra displayed on the scanner are scaled based on the highest peak. If there is a huge amount of lipid in the spectra, the scanner will scale the remainder of the peaks to the height of the lipid peaks. If the lipid peaks are very tall, the remaining peaks will be reduced and therefore become unreadable. In certain pathologies this is an important factor and therefore the strategy is to move away from the necrosis to the edge of the lesion.
- *Blood:* Blood contains heme-iron which is paramagnetic and will destroy signal coming from brain tissue. Post-surgical locations or highly necrotic centers can pool blood which makes spectra unobtainable or at the very least very difficult to read due to decrease in SNR.
- *Open space:* Within the brain there can be areas of open space such as in air sinuses adjacent to the temporal lobes. In cases of resection, there can be areas of the brain "missing." These should be avoided not only because of the possibility of blood; the large air spaces cause field inhomogeneity problems. You must be sure to check through all slices of the images to ensure that your voxel does not contain any of the air space.
- *Cerebral spinal fluid (CSF):* While having some CSF in the voxel can be unavoidable, it is important not to have CSF occupy more than 40% of the voxel. CSF has no brain metabolite signal, therefore, if CSF comprises



```

Fig. 7. Example of lipid overwhelming the spectrum. With the lipid peaks overwhelming the spectrum, it is very difficult to ascertain if there is an increase in Cho for diagnosis. Although this is a short echo acquisition, enough lipid within the voxel can negatively impact a long echo neurospectroscopy exam as well. This is a common problem when dealing with focal neurospectroscopy where the voxel is often placed in the center of a necrotic lesion as shown in the MRI at the top. The necrosis contains a great deal of lipid which would overwhelm the spectra, reducing its diagnostic value. The key to avoiding this artifact is to move the voxel to the edge of the lesion where there is not as much lipid signal from necrosis.

a large part of your voxel, the total signal is reduced causing a very "noisy" spectrum. CSF does, however, contain lactate (1–2 mM) and glucose, which could be misinterpreted as an indicator of pathology. Nevertheless, it is better to include CSF in your voxel if it helps avoid the four areas listed above.

As described in the section dealing with voxel size, partial volume is one of the attributes of focal spectroscopy that can be optimized with voxel position. This is especially the case in large areas of interest that should not or cannot be acquired with a single large voxel. In this case, one must use a smaller voxel that brings into question where to place the voxel: In the middle of the area of interest or at the edge? Studies have shown that in cases such as brain tumors, it is better to obtain spectra from the edge of the lesion away from the brain. This is due to the necrotic centers often found in tumors which as described above, can cause serious problems with your acquisition. By obtaining spectra from the edge you may not have complete partial volume but you guarantee yourself a more interpretable spectra. You should choose a voxel that has the highest partial volume while avoiding the areas stated above.

A frequently asked question is whether it is necessary to obtain a second spectrum that is contralateral to the focal voxel. This is obviously quite useful to the radiologist so that there is a comparable "normal" spectrum with which to compare the pathological one. The danger of blindly trusting such a spectra is that in some pathologies, the changes in metabolism are not limited to the region of interest. For example, when trying to distinguish radiation necrosis from tumor, it is assumed that the contralateral region to the tumor is "normal." However, studies have shown that radiation therapy itself causes global changes to the brain and therefore would affect the metabolite ratios of "normal" spectra. We recommend that one use this technique for the first generation of cases. As the radiologist becomes more familiar with the spectral patterns in different areas of the brain, it will not be necessary to provide a so-called normal contralateral spectrum.

Consistency

Once again we would like to reemphasize the importance of being consistent and reliably following protocol. When training our own technicians, we follow a set pattern that has allowed us over the course of a decade to acquire spectra with a high degree of reproducibility and very low variability. For example, one patient who has been examined every year for the past 6 years has demonstrated spectra with a reproducibility of less than 5% despite several upgrades and different technologists running each exam (Figure 8). The goal in mind is to try to achieve this level of consistency. This way, any biochemical changes can be attributed to pathology and not to changing acquisition parameters.

With the global paradigm, it is essential to be consistent. By following the protocol, you can ensure that your results will be comparable to published data utilizing the same technique. With the focal paradigm, it is not quite

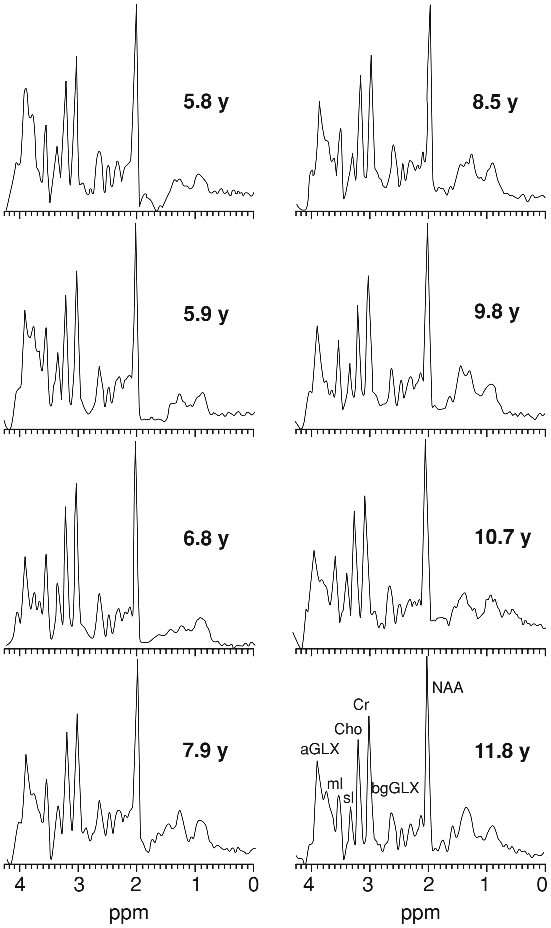

Fig. 8. Sequential neurospectroscopy: Monitoring the effects of treatment over a period of six years. Despite several system upgrades and different technologists, the consistent normal spectra obtained in a child with x-linked adrenoleukodystrophy has convinced physicians to keep the patient on Lorenzo oil treatment rather than the highly dangerous bone marrow transplantation he would have otherwise received. These spectra were all acquired with the gray matter protocol described in Protocol 1.

as simple: all of these parameters do interact with one another. In particular, voxel size and number of averages are very dependent on one another and will require adjustments if either is altered. If you decrease your voxel size by a factor of two (one-half) you increase the number of averages (to obtain the same level of SNR) by a factor of four! This in turn causes the exam to last longer which, in turn, can jeopardize the exam as a whole because the patient may become restless and move the head (moving your voxel to an entirely different location!) or worse, demand to be released from the scanner. How do you balance all of these elements?

We recommend starting with a "basic" protocol for all exams (this of course does not apply to global protocols which should not be changed) and then adjust the parameters according to the situation. Factors such as sequence and echo time should NOT be changed unless absolutely required. This is critical in maintaining consistency of spectra from patient to patient. Voxel size should be set at a default size: 8 cc is generally system's default size on most 1.5 T scanners. If you can acquire good quality spectra with 128 averages at 8 cc, then simply adjust averages according to size. Voxel position does not necessarily negatively affect the other parameters unless positioned incorrectly. Therefore, take special care in choosing the best area possible.

Multivoxel Spectroscopy

All of the rules described above also apply to multivoxel spectroscopy (a.k.a. Chemical Shift Imaging (CSI), Metabolite Maps, Spectroscopic Imaging, etc), the main difference being that instead of just an excitation volume (voxel) you must also consider the number of phase and frequency encoding steps as well as the field of view (FOV). The approach to multivoxel neurospectroscopy is more similar to imaging. It is easiest to imagine the FOV defining the image area as shown in Figure 9. The frequency and phase encode steps then divide the FOV into smaller boxes which can be reproduced as individual spectra. The increased number of encoding steps and the smaller the FOV, the higher the resolution you will have for each individual spectra. For example, a 16 × 16 cm FOV using 16 frequency and 16 phase encode steps will provide a volume of 1 cc per voxel when using a thickness of 1 cm. The same FOV, with the number of encoding steps increased to 24 will then give a resolution of 0.44 cc. This of course comes with the time penalty of increasing scan time approximately from 5 to 10 min. However, there is a signal gain by increasing the encoding steps. Depending on the resolution you require, you want to set your protocol accordingly. We give our standard protocol at the end of the next section.

The excitation volume is therefore equivalent to the voxel where the same rules in voxel positioning apply as shown in Figure 9. However, the number of averages and voxel size are no longer correlated since scan time is completely dependent on the number of encoding steps. It is a common mistake to try to use the largest volume possible (since there is no impact on time and all of the data from that region is acquired anyways), however, we have found that this affects the line width of the scan. We

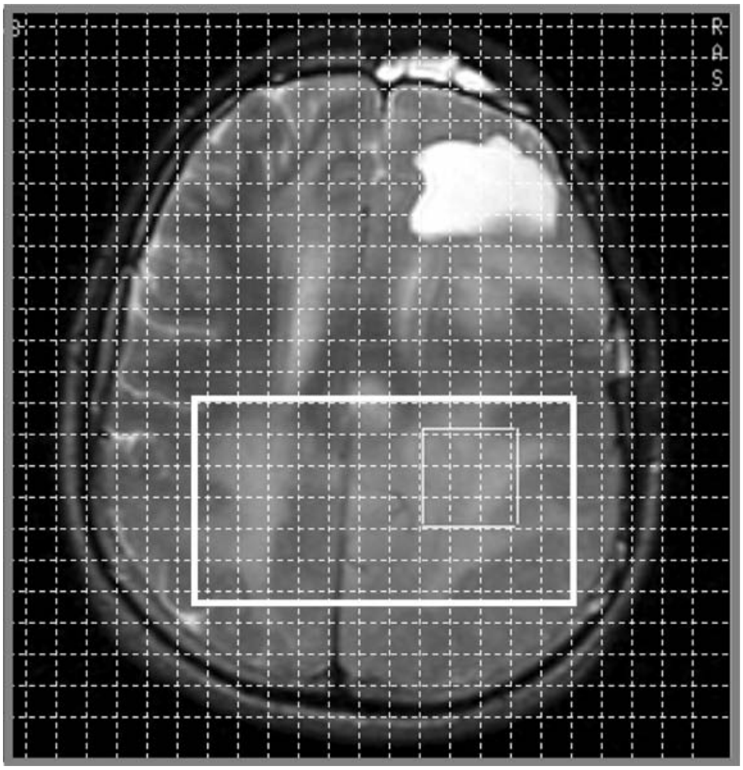

Fig. 9. Multivoxel neurospectroscopy. This is an example of short echo multivoxel neurospectroscopy in a patient with acute disseminated encephalomyelitis. The FOV is the entire image as indicated by the thick gray box. The FOV is then split into smaller voxels by phase and frequency encode steps as represented by the dotted line boxes. The excitation volume, or the voxel, is indicated by the thick white box. Note that the voxel does not acquire excitation from the entire brain but rather just from the region that is clinically relevant which are the hyperintense areas in the posterior aspect of the brain.

therefore recommend that the voxel only encompasses the region that you are interested in and no larger.

The third aspect of multivoxel neurospectroscopy that is different is the display of the data. Initially, multivoxel had the great promise of eliminating the need for interpreting spectra by using "metabolite maps"—color maps that correspond to the peak height of the metabolite over the area of excitation. However, we found that not only are the metabolite maps not reliable, they could be actually misleading. This has to do with the fact that it does not correct for overall signal strength. In other words, the high choline observed may not be due to increased Cho in the region but simply due to an increase in all MR signals from a homogeneous region. We therefore rely on the individual spectra for analysis. This presents a problem in itself since the radiologist will not want to comb over hundreds of spectra generated by each multivoxel exam. Instead we describe a "speed reading" technique where only select regions (those that are most clinically relevant) of the spectra are displayed. The region of interest is displayed with a summed spectrum and the individual spectra, usually in an easy-to-read 3 × 3 grid. This also has the benefit of providing quality assurance by generating a summed spectrum from the same voxel region as the single voxel exam. In this way, we find the most efficacious exams to include both single and multivoxel neurospectroscopy both using the same echo time.

Part II: Neurospectroscopy Protocols

Clinical Protocol Decision Matrix

All of the following protocols have been time-tested and proven to provide all of the necessary information required for the accurate diagnosis of disease. They are based on peer-reviewed published studies demonstrating efficacy with these techniques. In addition, the protocols are designed to be practical for the demands of a clinical practice.

The first step in applying these protocols is to know which diagnostic test is most efficacious for a disease process. With that in mind, the following section details a decision matrix for deciding which protocols should be used in each patient case. Although the list is not all inclusive, it provides a framework from which exam planning

Table 1: Clinical protocol decision matrix

Diagnosis	Protocol
Dementia, memory loss	Standard GM/WM
Frontal lobe Lewy body dementia	+Frontal GM
Focal Lesion (tumor, recurrence)	Focal SV-MRS, CSI
+Contrast	+T_1w, T_1w + c, MRS OK after Gad
vs. Stroke	+DWI, voxel in center of lesion and rim
vs. Abscess	Voxel in the center of lesion, maximize PV
Radiation necrosis vs. recurrence	Voxel at the edge of the lesion
Demyelinating disease, white matter disease	Standard WM
Multiple sclerosis w/o lesions	Standard WM
Multiple sclerosis w/ lesions	Lesion if >3 cc, CSI if <3 cc L or R WM in normal appearing WM
Epilepsy	Standard GM/WM
Mesial temporal lobe epilepsy	+L/R temporal lobe
Known focus	Focal SV (bilateral)
Parkinson's/Huntington's disease	Standard GM/WM, L/R BG
Hepatic encephalopathy	Standard GM/WM (earliest changes in WM)
Global hypoxia	Standard GM/WM
Trauma	SV MRS away from blood/lesions
Possible hypoxia	GM
No hypoxia	WM
Systemic diseases, unknown not focal	Standard GM/WM

can be initiated. The decision matrix also provides a basis for dynamic decision making at the time of the exam. For example, discoveries made at the time of the exam may necessitate additional tests to be run. It is important to note, however, that input from the managing physician at the time of the exam provides the greatest diagnostic precision.

Protocol 1: Standard Gray Matter (GM) or Posterior Cingulate Gyrus (PCG)

1. Position the patient in the scanner as indicated in Section 1 (Figure 3).
2. Acquire localization images for spectroscopy
   a. For single-plane acquisition scanners:
      i. Slice thickness + Interspace = 5.0 mm. That way you can place your voxel on the center slice and check two slices up and two slices down to ensure that your voxel does not fall into any bad areas.
      ii. For ease of landmarks, we suggest using the axial plane.
   b. For three-plane acquisition scanners:
      i. Choose a sequence that shows the best contrast between gray and white matters. We generally use a T_2w image.
3. Set up your neurospectroscopy scan parameters:
   a. Pulse sequence: PRESS
   b. $T_E = 35$ ms
   c. $T_R = 1500$ ms
   d. Voxel size = 20 × 20 × 20 mm
   e. Number of averages = 128
4. Place your voxel using the following landmarks:
   a. Center across falx at level 1 cm above posterior commissures of corpus callosum.
   b. Start inferior one slice (5 mm) above the slice with the (a) internal capsule, (b) angular artery in sylvian fissure, (c) occipitoparietal fissure, (d) vein of Galen, (e) internal cerebral vein, and (f) frontal horn of lateral ventricle. *Note:* If the head is tilted not all of these landmarks may be visible.
   c. By choosing a voxel shape of 20 mm in A/P and 20 mm in R/L, most of the tissue within the voxel is GM.
   d. Review above and below center position at least two slices (for 5 mm MRI slice thickness and 20 mm voxel slice thickness) for single-plane acquisitions. Check all three planes to ensure that you stay away from the skull, white matter (particularly the corpus callosum), and ventricles (Figure 10).
5. *Prescan routine:* this is different on different platforms. What is performed, however, remains the same:

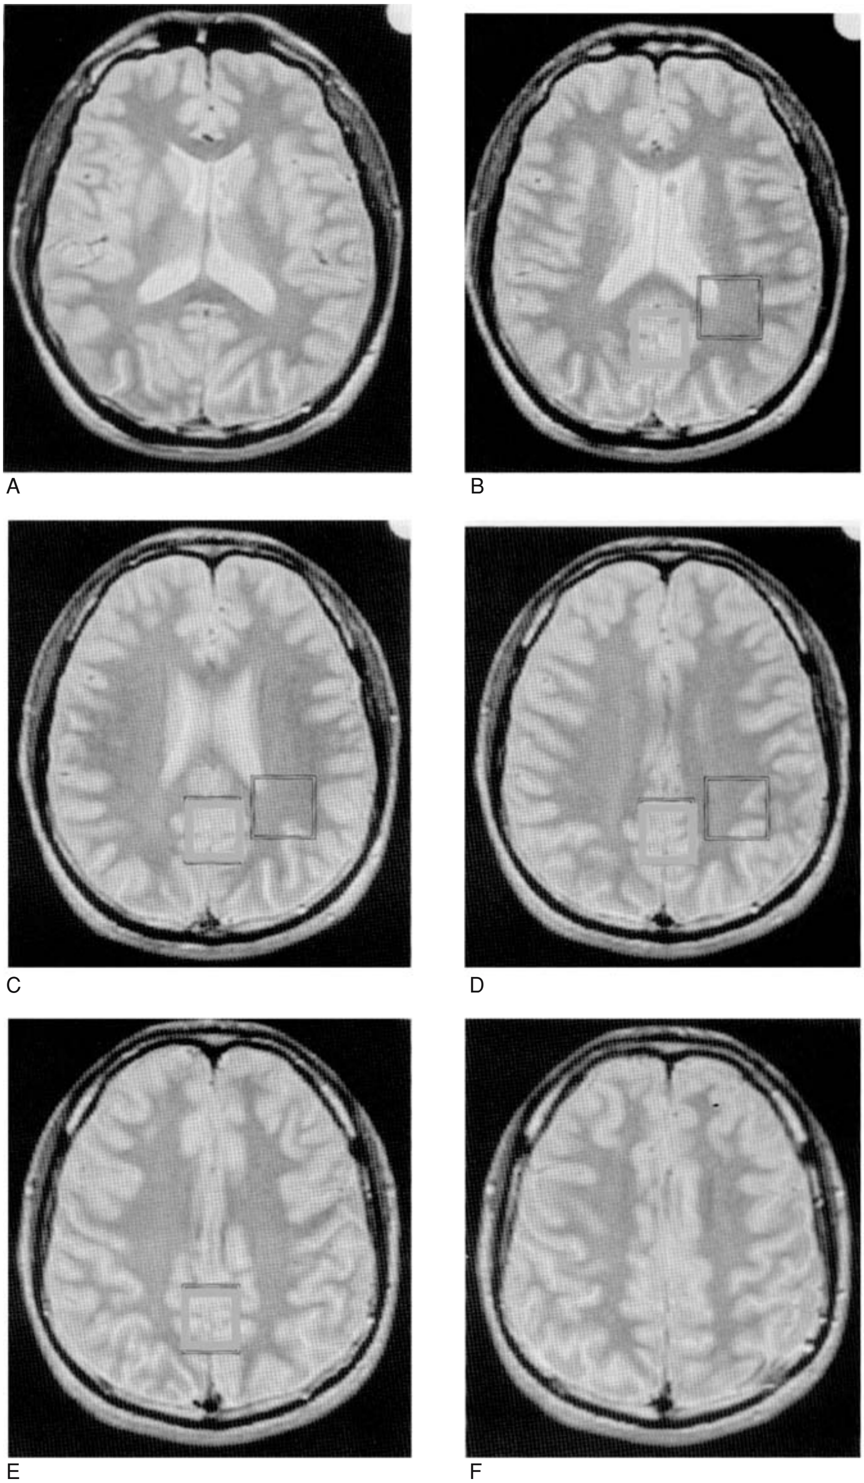

Fig. 10. Gray matter voxel position. Note that you should not only have a well-placed center slice but keep in mind all other slices as well.

   a. *TG optimization:* Optimize for the greatest amount of signal.
   b. *Water suppression:* You are better off to slightly under-suppress than to over-suppress.
   c. *Shim:* This is the most critical factor, the line width (sometimes represented as FWHM, full width half max of the water peak) should be less than 7 Hz at 1.5 T.
6. Acquire the scan.
7. Reconstruct the data. Generally this is automated, however, the routines include spectral apodization, fast Fourier transform, baseline corrections, and peak fitting.
8. Filming the data:
   a. Show the voxel location in three dimensions—"3D"
      i. Three-plane localizers, that is fairly straightforward. You simply place a voxel in each plane as shown.
      ii. For single-plane localizers, you will need to prescribe the center slice and then two slices above and below to demonstrate the voxel position in 3D.
   b. Show the reconstructed spectra. Label as GM or PCG.

Protocol 2: Standard White Matter

Repeat Protocol 1 with just a modification to step 4:

4. Place your voxel using the following landmarks:
   a. Stay in largely white matter, but allow up to 25% of GM.
   b. Landmarks are the
      i. Center posterior rim of left (right) lateral ventricle
      ii. 1–1.5 cm above posterior commissures of corpus callosum.
   c. Review above two and below at least two slices (for 5 mm MRI slice thickness and 20 mm voxel slice thickness).
   d. The S/I center position should be not more than 0–5 mm (superior) off from the GM center (Figure 11).

Protocol 3: Frontal GM

Repeat Protocol 1 with the following modifications:

4. For placement of the frontal GM voxel, use the axial T_2w MRI as shown in Fig. 12 (FGM is the box with the dotted lines, ignore the posterior boxes).
   a. Place the single voxel neurospectroscopy in the frontal GM just as you would for the PCG.
   b. You must tuck it in between the anterior skull and the anterior corpus callosum.
   c. Avoid being close to the nasal sinuses as well as CSF space.
   d. Try not to include the frontal white matter.

On GE systems: change FreqDIR to L/R instead of A/P. This is an important step as it reverses the gradient order which allows for better shims (Figure 12).

Protocol 4: Hippocampus/Temporal Lobe

1. For scanners that utilize the true coronal plane, make sure that the patient head is as straight as possible. If the head is tilted to the left or right, it will make voxel placement and/or comparison more difficult.
2. Acquire coronal localizers that can easily differentiate the hippocampal GM and temporal lobe white matter.
3. Set up the following parameters:
   a. Pulse sequence: PRESS
   b. $T_E = 35$ ms
   c. $T_R = 1500$ ms
   d. Voxel size = 15 × 15 × 30 mm (30 mm thick in the S/I direction)
   e. Number of averages = 256
4. Find the slice where the brainstem is apparent (as shown in Fig. 13) and place the voxel in the hippocampus. Try to capture as much of the GM of the hippocampus as possible. This will be your center slice.
   a. Check three slices up and three slices down—you may have to shift the center slice to capture as much of the hippocampus as possible.
   b. Make sure to not fall outside of the temporal lobe! Check your bottom left corner of the voxel for the left-sided voxel and bottom right corner for the right.
   c. Try not to include any of the inferior ventricles (Figure 13).
5. Prescan routine: It is absolutely essential that the line widths are less than 7 Hz. In many cases, you may need to check the line width and move the voxel to try to obtain a better line width. This is the most challenging aspect of hippocampal spectroscopy and why measurements from this region have a high variation.
6. Acquire data.
7. Prescribe a voxel that is exactly contralateral to the previously acquired voxel. This is also difficult but you must be absolutely precise in order to ensure comparability between the two spectra.
   a. Remember to take into account any tilt of the patient to ensure that the same regions are measured.
   b. For single-plane scanners, you may have to prescribe your center slice on a different slice if the patient's head is tilted to the left or right (reference the eye balls to check for head tilt).

Fig. 13. Left and right hippocampal voxel position. Note how the voxel may not be on the same S/I level due to some minor head tilt. Not shown are the other slices that are 15 mm above and below this center slice.

Protocol 5: Multivoxel Neurospectroscopy (For Focal Use Only)

1. Position the patient in the scanner as indicated in Section 1 (Figure 3).
2. It is recommended that a single voxel exam precedes the multivoxel exam for the most efficacious exam. Proceed with focal techniques described in the first section.
3. Acquire localization images for spectroscopy
   - c. For single-plane acquisition scanners:
     - i. Slice thickness + Interspace = 5.0 mm. That way you can place your voxel on the center slice and check two slices up and two slices down to ensure that your voxel does not fall into any bad areas.
     - ii. For ease of landmarks, we suggest using the axial plane.
   - d. For three-plane acquisition scanners:
     - i. Choose a sequence that shows the best contrast between gray and white matters. We generally use a T_2w image.
4. Set up your neurospectroscopy scan parameters:
   - e. Pulse sequence: PRESS-CSI
   - f. $T_E = 35$ ms
   - g. $T_R = 1000$ ms

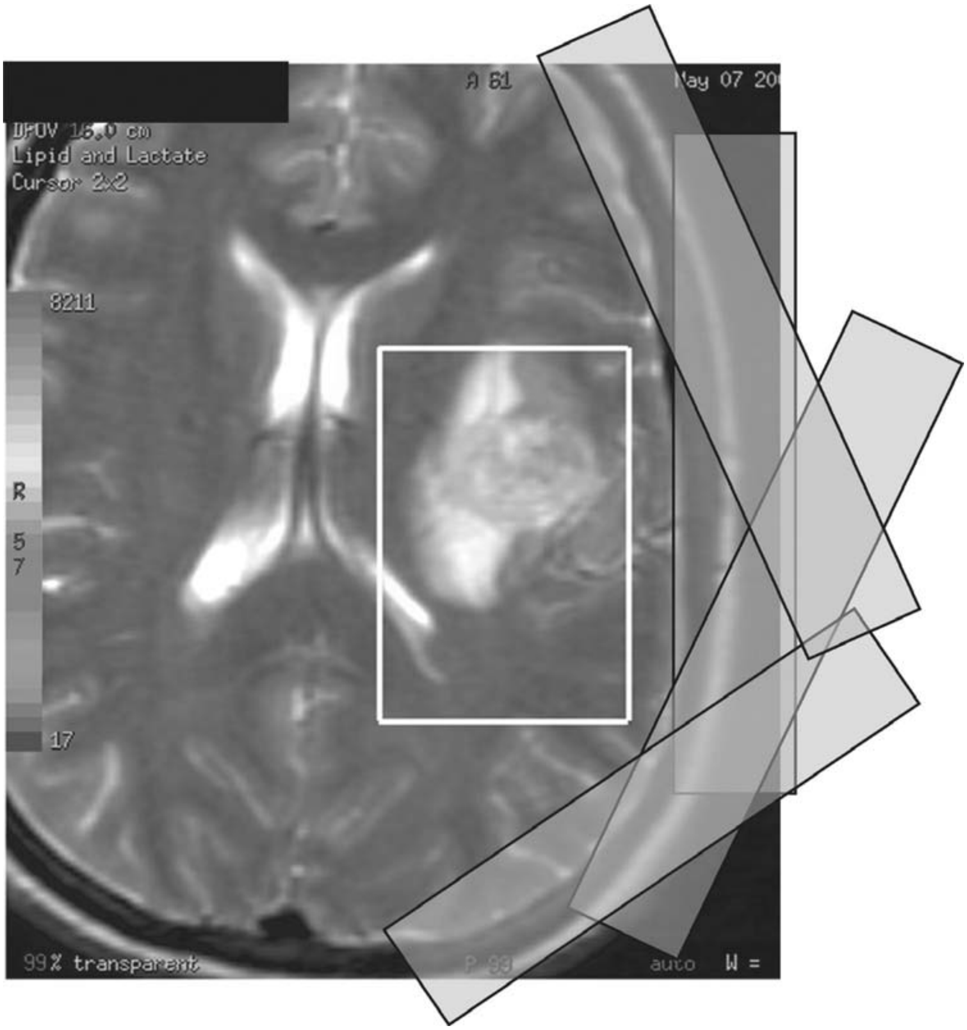

Fig. 14. Saturation band and excitation volume placement. If available on your scanner, additional saturation bands can be placed to regions close to the excitation volume to avoid lipid contamination from the skull.

   h. Phase encode = 24
   i. Frequency encode = 24
   j. FOV = 24 × 24 cm
   k. Slice thickness = 10 mm
   l. NEX = 1
5. Prescribe the excitation volume voxel around the area of interest (i.e. lesion) and a bit more. Make the size relevant to what you are looking for. Use the same center slice as that of the single voxel exam. Use the same care described above in not placing the excitation volume too close to the skull and other areas of inhomogeneity.
6. If they are available on your scanner system, place saturation bands over skull closest to the voxel in order to avoid any lipid contamination. Make sure that the saturation bands do not intersect with the excitation volume. The saturation bands are used to cut out the residual water and any lipids surrounding the skull (Figure 14).
7. Prescan routine: In the case of multivoxel neurospectroscopy, since the volumes are larger, the line widths will not be as low as those for single voxel. Generally, a line width of <11 Hz is acceptable.
8. Acquire the data.

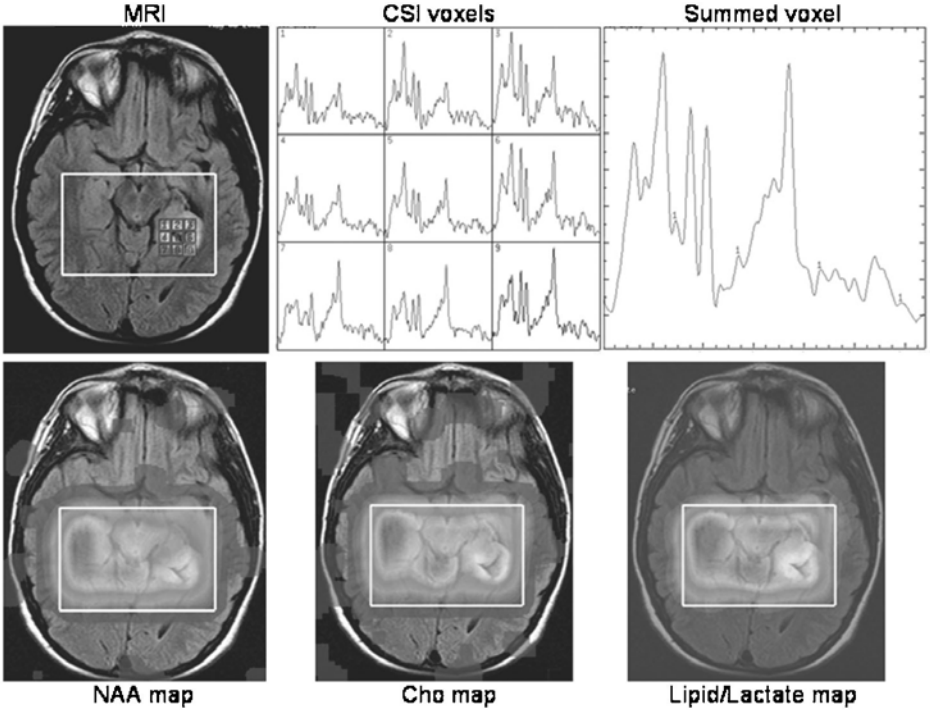

Fig. 15. Filming multivoxel neurospectroscopy for "Speed Reading." This case of a temporal lobe lesion demonstrates the value of multivoxel short echo neurospectroscopy. The region of interest is indicated on the images (top left) from which the summed spectrum is shown (top right). To benefit from the fine resolution of multivoxel neurospectroscopy without the obfuscation of hundreds of spectra, the individual spectra from the region of interest are also shown (top middle). The bottom row demonstrates the metabolite maps generated from this same exam. They are not particularly diagnostic despite excellent spectral quality as demonstrated in the top row. These spectra demonstrate a high mI signal which indicates a low-grade tumor which would have been missed if it had been acquired with long echo TE or relying on high Cho alone. The results were confirmed by autopsy. (See also Plate 82 on page XIII in the Color Plate Section.)

9. Data analysis: it is best to visualize the multivoxel as soon as possible. Users will want to check for quality first and then use the multivoxel results for planning a confirmatory single voxel exam. The reasons why a second single voxel result is recommended are a) it provides confirmation of multivoxel results, and b) the single voxel technique is much more robust and not prone to artifacts that could mislead the diagnosis.
10. When filming the multivoxel results, the "speed reading" technique is used where multiple regions from the excitation volume are selected and summed as well as individual spectra from that region are shown (Figure 15, top row). This allows for quick yet detailed inspections of multiple data points. It is important to also film the regions from which single voxel were acquired to provide quality assurance of your multivoxel data.

Summary

Once the above routines are well established, they can be enshrined in a protocol on your scanner. This limits the number of variables—and hence sources of error—as well as greatly speeding the diagnostic scan. In our clinical practice, technologists must go through a training routine before they are allowed to run patients. Initially they run "phantom" studies: acquiring spectra on a container with different concentrations of chemicals similar to those found in the brain. This can be purchased from the manufacturer or the Spectroscopy Institute (http://www.spectroscopy.org). This will enable the technologist to become familiar with the controls and the protocols. Secondly, they acquire several spectra from volunteers. This allows the new technologist to build up a working knowledge of different brain regions and their biochemistry as well as providing the group with a larger base of their own "normal values." If this is not possible, then close supervision of the acquisition on patients is necessary. Quality control is essential at this stage. Ensure that they are following protocol religiously. At the end, you will have a well-trained technologist in spectroscopy.

This chapter was written with the assumption that the reader will have a basic familiarity with clinical applications of neurospectroscopy. Recommended reading would include "Magnetic Resonance Spectroscopy Diagnosis of Neurological Diseases" by Else Danielsen and Brian D. Ross (Marcel Dekker, 1999). Additional resources include the Clinical MR Spectroscopy Course offered annually by Dr. Brian Ross and his staff at Huntington Medical Research Institutes (http://www.hmri.org) as well as on-site technologist training course offered by the Spectroscopy Institute available throughout the year (http://www.spectroscopy.org). The manufacturers such as General Electric Healthcare, Siemens Medical Systems, and Philips also offer applications training and courses that cover spectroscopy throughout the United States, Asia, and Europe.

Acknowledgments

All of the experiences detailed above would not have been possible without the guidance and support of Dr. Brian D. Ross at Huntington Medical Research Institutes. He and the many scientists that have been under his tutelage have truly brought the science to the bedside by developing neurospectroscopy as a clinical diagnostic tool. Drs. Stefan Bluml, Else Danielsen, Thomas Michaelis, Thomas Ernst, and Roland Kreis are among the many that have contributed to the clinical practice of neurospectroscopy.

Introduction

Brain infections are often acute and potentially life-threatening diseases of immunocompromised and healthy hosts. Rapid, accurate, and safe diagnostic methods are essential to initiate optimal treatment and reduce mortality from brain infections. We will focus here on focal brain infections as an example of the diagnostic potential and limitations of magnetic resonance imaging (MRI) and spectroscopy (MRS) methods. Particular attention will be paid to distinguishing between tumors and infective lesions. Different types of infections will be discussed.

Brain lesions are usually diagnosed after biopsies are taken. A definitive diagnosis is still typically established by culture of bacteria from pus obtained after neurosurgical biopsy, or inferred by culture of infected material from other body sites. Computerized tomographic (CT) and MRI methods have reduced mortality by improving the detection and localization of brain lesions over the last decades [1,2]. Typically, necrotic or cystic tumors, tumorfactive demyelinating lesions, and cerebral abscesses show similar appearances using conventional radiological methods. The use of diffusion-weighted images, perfusion MRI and MRS have been suggested for differential diagnosis of these pathologies [3–5]. However, differential diagnosis of post-contrast ring-enhancing cerebral lesions continues to be a challenge, as such lesions include glioblastoma, metastasis, pyogenic abscess, subacute ischemic infarction, resolving hematoma, and demyelinating disease [3,6–8]. This becomes a particular problem when other indications of infections (like fever) are missing and microbial culture from body fluids is negative, as can be the case in up to 50% of infective lesions [2]. In addition, case reports are relatively sporadic and the microbial spectrum is diverse.

Pathological, clinical, and diagnostic aspects of brain infections, and their diversity, have been addressed in a number of reviews and are beyond the scope of this review [1,2,6,9]. Although detailed descriptions of the fundamentals of MR techniques have been addressed elsewhere [6,10], essential methods will be discussed and their application will be demonstrated, using the example of focal brain infections.

Scenarios that need to be addressed by non-invasive diagnostic tools include: (1) the differentiation between infective lesions and other pathologies like glioma and (2) the identification of the infection-causing microorganisms.

Magnetic Resonance Techniques

The physical basis of MRI and MRS has been reviewed by numerous authors (for example Ref. [10]). In order to access the most appropriate MR techniques one has to consider the physical nature of an infective brain lesion. A "true" abscess consists of an abscess capsule, containing fibrous material and chronic inflammation cells, and a central cavity filled with pus. Pus is of variable viscosity and consists of dead and dying polymorphous cells (leucocytes), living and dead microorganisms, tissue debris, and other components of inflammation (edema fluid and fibrin) [1,2]. In contrast to "true" abscesses, some focal infections (parasitic, fungal) lack an abscess wall. In order to distinguish between abscesses and other focal brain diseases and to distinguish between various types of focal infections the following properties are of interest for diagnosis: proton density, spin–lattice relaxation time (T_1), spin–spin relaxation time (T_2), flow, diffusion, chemical composition, and variation in uptake of contrast agents. For clinical diagnosis, it is important to select protocols that are rapid, as some of these patients are critically ill. Short protocols increase patient comfort, allow

Graham A. Webb (ed.), Modern Magnetic Resonance, 1005–1013.
© 2008 *Springer.*

additional studies, and decrease motion artifacts. It is also important to suggest protocols that can be implemented on various hardware platforms, including older MR systems that are common in developing countries where the cohort of abscess patients is large.

At present, two-dimensional (2D) multislice images are commonly used in routine diagnosis. The most widely used pulse sequences are based on spin-echo sequences. The main drawback of the spin-echo sequence is a relatively long acquisition time. Alternatively to spin-echo T_1-weighted images, inversion recovery results in stronger T_1 weighting due to an initial 180° pulse followed by an evolution time, during which the inverted spins relax back to $+Z$ according to T_1. By choosing a specific evolution time that suppresses lipid resonances, T_1-weighted images can be acquired with inversion recovery spin-echo sequences that suppress lipid signals. Combining inversion recovery with T_2-weighted spin-echo sequences can be used to attenuate otherwise hyperintense signals from fluids [fluid-attenuated inversion recovery (FLAIR)]. FLAIR permits the detection of CNS lesions that are adjacent to regions containing fluids (e.g. CSF). Significant improvement of lesion-to-CSF contrast has been achieved using FLAIR [11].

Reduction of repetition times (TR) is possible with gradient echo imaging. Gradient echo images are particularly sensitive to field inhomogeneities. Instead of 180° pulses, gradients are used to refocus the signal. Adjustment of pulses is therefore less critical than in spin-echo sequences. Spin-echo sequences are sensitive to T_2 effects, gradient echo sequences are sensitive to T_2^* effects. Due to the sensitivity to field inhomogeneity, the quality of gradient echo imaging is usually lower compared with spin-echo sequences.

A more rapid version of spin-echo sequences is fast-spin-echo or turbo-spin-echo imaging [12]. The total scan time is hereby reduced by traversing through several phase-encoding levels during each TR. Thus, several echoes are collected during each TR. Fast-spin-echo methods require rapid switching of gradients, imposing considerable strain on the hardware. The large refocusing angles make constraining RF power a challenge. Nutation angles of much less than 180° can overcome this problem [13]. Other rapid acquisition methods include gradient echo fast-low-angle-shot (FLASH) [14] and echo planar imaging (EPI) [15,16]. In EPI the entire matrix is acquired in one excitation with multiple phase-encoding gradient echoes. The penalty of the rapid data acquisition is a relatively low image quality. EPI is of great importance for applications that do not necessarily require a high resolution such as functional MRI or diffusion-weighted imaging (DWI) [17]. The drawback of EPI is image distortion, dropout, blurring, and signal loss [18]. EPI quality and resolution can be improved by reducing the readout time (parallel imaging or half-Fourier techniques) [19].

Acquisition time gained by the application of rapid pulse sequences can be reinvested in improving the quality of the image. This applies to increasing the signal-to-noise ratio (SNR) by averaging more transients, increasing the resolution to reduce partial volume effects by acquiring a larger data matrix or by applying stronger T_2 weighting using longer TR and TE values.

Differences in tissue molecular self-diffusion due to translational motion can be monitored by application of strong magnetic field gradients. Molecular motion between the application of these gradients results in dephasing of the MR signal. Diffusion-weighted images can be acquired by varying either the gradient strength (G), the gradient length (δ), or the separation (Δ) between two read out gradients (dephasing and rephasing of water protons) [20]. The so-called b value ($b = (\gamma G \delta)^2 [\Delta - \delta/3]$) describes these variables in comparable form. In diffusion-weighted images, regions of hyperintensity represent restricted diffusion. Maps of apparent diffusion coefficients (ADC) can be calculated by acquisition of a number of images in which either G, δ or Δ have been incremented systematically. Due to time constraints for the acquisition of a series of images, diffusion-weighted EPI is usually used to obtain ADC maps. It has become common practice to use only two b values for the calculation of ADCs. However, in order to avoid an overestimation of the ADC, multiple points (b) should be used for more accurate calculations [4,21].

Perfusion-weighted MR imaging (PWI) exploits signal changes following the passage of a contrast agent or labeled spins through the cerebrovascular system. A series of images is acquired in short intervals from which relative cerebral blood volume (rCBV) maps are calculated. The CBV is proportional to the area under the contrast agent concentration–time curve. Fast acquisition methods are required for PWI (rapid gradient echos, EPI).

Magnetization transfer (MT) has been used to increase tissue specific contrast in various diseases [22,23]. Selective saturation of signal contributions from protons with very low T_2 values (broad lines due to decreased mobility) can be achieved by off-resonance irradiation. MT from the saturated protons to mobile protons results in decreased signal intensity and produces substantial changes in contrast [24].

Localized *in vivo* MRS is probably the most powerful tool for determining the chemical composition of an object of interest non-invasively. In contrast to MRI methods, chemical shift information for the acquisition of metabolite profiles is acquired from a volume of interest (VOI), suppressing unwanted signals from outside the VOI. Although, ^{31}P and other nuclei like ^{13}C are increasingly studied (for example [25–27]), the most commonly used method for clinical diagnosis is ^{1}H MRS. From the relatively large number of MRS protocols [28], single VOI spectroscopy is most useful when studying lesions that are magnetically distinct from surrounding tissue. Although, chemical shift imaging (CSI) provides a matrix of spectra over relatively large regions within a short time, it is less suitable for the acquisition of high-quality spectra of focal lesions due to difficulties of shimming over a heterogeneous region. The two main pulse sequences used for single VOI MRS are point-resolved spectroscopy (PRESS) [29] and stimulated echo acquisition mode (STEAM) [30]. PRESS uses an excitation pulse ($\pi/2$) and a double echo and STEAM uses stimulated echoes. In general, PRESS results in higher SNRs but requires more precise pulse calibrations to suppress signal from outside the defined VOI. It can be distinguished between localized MRS that has been acquired with relatively short echo times (TE $<$ 35 ms) and with long echo times (TE $>$ 130 ms). The latter has the advantage of suppressing contributions from compounds with short T_2 relaxation times like lipids and macromolecules that would otherwise mask resonances from small metabolites in low concentrations. On the other hand, those compounds may be of diagnostic value. MR spectra can be applied for the quantification of metabolites [31,32].

More recently, methods from high-resolution (*ex vivo*) MR spectroscopy like ^{1}H, ^{1}H COSY and J-resolved MRS have been applied to *in vivo* assignment of resonances [33,34].

Contrast Enhancement

MR contrast agents modulate T_1 and T_2 relaxation times of water molecules inside the organism. Intravenous administration of gadolinium (Gd)-based contrast agents results in signal enhancement in T_1-weighted images in areas of accumulation of the substance. In the case of brain lesions, this most commonly reflects an increase in blood volume or a breakdown of the blood–brain barrier. Post-contrast hyperintensity of a perilesional ring is common in cerebral abscesses in the capsule stage as well as cystic and necrotic brain tumors [most commonly glioblastoma multiformes (GBMs)]. This makes differentiation between abscess and tumor difficult based on conventional contrast agents.

Most recently, responsive contrast agents have become more and more important. These contrast agents are usually responsive to chemical modification or specific binding to receptors, resulting in an activation or accumulation of the contrast agents at the targeted site [35,36]. One example in cancer diagnosis is the combination of iron oxide particles with ligands that bind to transferin receptors, resulting in accumulation of contrast agent in glioma cells [36]. Similarly, antibody–polylysine Gd chelates or Gd chelates targeting cell surface molecules have been suggested for specific visualization of tumor cells [37–39].

Ultra-small paramagnetic iron oxide particles (USPIOs) generate large susceptibility effects in surrounding tissue. This results mainly in shortening of T_2 and T_2^* relaxation times and subsequent hypointensity in respectively weighted MR images [40,41]. Labeling of phagocytes with USPIOs has been used for cell tracking *in vivo* [42]. Krieg *et al.* suggested the use of USPIOs for the detection of inflammatory processes as they result in the accumulation of large numbers of phagocytes [43]. This hypothesis has been proven by the utilization of *in vitro* labeled neutrophils in an animal model of induced abscesses. Intravenous administration of USPIOs was subsequently shown to differentiate between normal tissue and abscess [44]. Phagocytosis of USPIOs by macrophages and neutrophils partly contributed to a persistent signal decrease in interstitial spaces of the abscess wall and perifocal granulation tissue. It remains to be seen if the use of USPIOs is useful in clinical diagnosis of abscesses, as other diseases such as stroke also result in inflammatory response and subsequent accumulation of iron labeled macrophages [42,45].

The utilization of iron or Gd-based contrast agents linked to antigens specific for particular pathogenic microorganisms is still an unexplored, potentially useful tool for the diagnosis and etiological characterization of brain infections.

Conventional MRI of Infective Brain Lesions

Pyogenic bacterial abscesses are the most common focal brain infections. Radiologically, a brain abscess appears in CT and MRI as a mass surrounded by edema, similar to brain tumors [9]. They are hypointense on T_1- and hyperintense on T_2-weighted MR images (Figure 1). The mature abscess often has a rim that is slightly hyperintense on T_1- and hypointense on T_2-weighted images. This has partly been attributed to accumulation of macrophages [9]. Post-contrast ring enhancement in T_1-weighted MRI is common in brain abscesses (Figure 1).

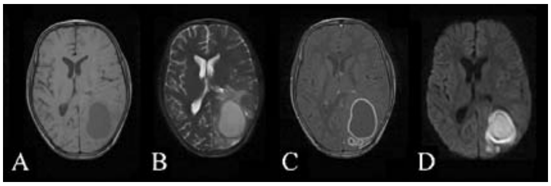

Fig. 1. Transverse MR images of a mixed bacterial abscess (*Streptococcus milleri* and *Bacteroides fragilis*). Images were acquired on a 1.5 T human MR scanner. (A) Hypointensity on T_1-weighted MR image (TR/TE = 660/15), (B) Hyperintensity and perifocal edema on T_2-weighted MR image (2200/80), (C) post-Gd contrast enhancement of a perilesional ring in T_1-weighted MR image (660/15) and (D) hyperintensity in a DWI ($b = 1000$ s/mm^{-2}) indicating restricted diffusion.

Features similar to pyogenic abscess were seen in intracranial tuberculoma [46,47] and focal infections caused by higher bacteria like *Nocardia* spp. [48,49].

Focal brain infections caused by fungi are less common. These infections can be caused by filamentous fungi (*Aspergillus* spp., *Mucor* spp.) or yeast and yeast like organisms (*Cryptococcus neoformans*, *Blastomyces dermatitides*, *Candida* spp., *Histoplasma capsulatum*). They differ from pyogenic abscesses as they do not necessarily form an abscess wall. The MR appearance of infections by filamentous fungi is often consistent with infarcts. Their hyphal elements lodge in intracerebral blood vessels, causing occlusions which result in microinfarcts and thrombosis. The actual infective lesions are not necessarily well defined. They show inhomogeneous hyperintensity on T_2-weighted images, surrounded by edema [50–53]. Hypointense peripheral rims have been reported due to blood products [51]. T_1-weighted images are often consistent with hemorrhages (hyperintense). Ring enhancement after administration of Gd contrast agent has been reported in some cases. The center of the lesion is often necrotic. Pituitary lesions due to *Aspergillus* spp. result in similar features to pituitary bacterial abscesses: a hypo- or isointense mass on T_1-weighted images, a hyperintense mass on T_2-weighted images and a peripheral contrast enhancing rim, which may also be features of pituitary tumor [54].

Similarly, yeast infections are characterized by isointensity [53,55] or hypointensity [9,53,56] on T_1-weighted images, hyperintensity on T_2-weighted images [9,52,53,55,56], and absence [53,56] or presence [52,53] of ring enhancement after Gd contrast. Some lesions show hypointense rings on T_2-weighted images due to the presence of macrophages [9].

Parasitic infections are caused by organisms that live part of their life cycle in a host. Parasites that cause focal brain infections in humans are most commonly *Taenia solium* larvae (causing cysticercosis), *Toxoplasma gondii* (toxoplasmosis), *Paragonimus* spp. (paragonimiasis), *Echinococcus* larvae (echinococcosis), amoebic infections, and others [57]. The appearance of lesions may change with development of the parasite and treatment. Many parasites can cause multiple lesions. They appear hypointense on T_1-weighted images, hyperintense on T_2-weighted images and show often no ring enhancement post-contrast [57–64]. Toxoplasmosis shows usually variable signal intensity on T_2-weighted images due to different amount of necrotic tissue, and post-contrast ring enhancement [64]. Later stages of paragonimiasis result in calcification and subsequent hypointense T_1- and T_2-weighted images [60]. Treatment of cysticercosis results in increased fluid content and immune response resulting in increased signal intensity on T_1, DW, and PW images and contrast enhancement [62].

Other MRI Methods

Diffusion

DWI provides unique information about translational molecular diffusion of water protons, which is also affected by the presence of cellular substructures [65]. Restricted diffusion within the cavity of a brain abscess, as opposed to the increased diffusion observed in cystic or necrotic tumors, was reported by Ebisu *et al.* [5]. This phenomenon was correlated with the high viscosity and cellularity of the respective pus samples. Further studies confirmed restricted diffusion in abscesses (Figure 1) [3,4,66]. However, the ADC values between and within these studies varied widely. Increased or unchanged ADCs have been reported for a number of abscesses [7,67,68]. Similar to these pyogenic abscesses, toxoplasmosis also resulted in increased ADCs [69]. These findings are not surprising as the viscosity of pus varies widely with the amount of inflammatory cells and microorganisms, the etiology and the age of the infective lesion (data not shown). In addition, restricted diffusion has also been found in cystic metastasis [7]. While decreased ADCs are highly suggestive of abscesses, they are not pathognomonic. A definite diagnosis of infective brain lesions cannot be based solely on DWI.

Perfusion

The main pitfall of PWI for the detection of brain lesions is that it can be inaccurate, where there is breakdown of the blood–brain barrier, which is the case in GBM and many infections [70]. In a low number of studies, it has been reported that intracranial infections resulted in a variable appearance in PWI, depending on the type of infection [71–73]. Pyogenic abscesses showed areas of increased rCBV in regions adjacent to the capsular rim in one study [71], suggesting that this may distinguish abscesses from solid tumors with areas of high vascularity, like high-grade GBMs and metastases [74]. Other studies have reported significantly lower rCBVs in abscesses compared to tumors, with lower rCBVs of the walls in abscesses compared to cystic/necrotic tumors [73]. However, these tumors can still be mistaken for abscesses based on PWI. Heterogeneous, hypervascular appearance of a significant number of tuberculomas has been reported, making differentiation between these lesion and tumors difficult [72].

This clearly indicates that more data are required to draw robust conclusions about the diagnostic value of PWI and DWI in distinguishing between subgroups of infective brain lesions and other pathological processes.

Magnetization Transfer

MT MRI for the diagnosis of infections is based on exchange of magnetization of protons from proteins with protons from water [22,75]. Pre-contrast MT spin-echo imaging was used for assessment of disease load in CNS tuberculosis and other infections due to better visualization of the lesions. Tuberculous lesions showed significantly lower MT ratios compared to pyogenic abscesses. Quantitative MT imaging was suggested in order to distinguish between various types of infective lesions [22]. A larger number of cases need to be evaluated in order to assess the influence of variable protein concentrations in abscesses.

Magnetic Resonance Spectroscopy

Although sophisticated MRI techniques are able to distinguish between certain infective lesions and tumors, cystic and necrotic gliomas can still be difficult to differentiate from abscesses. MRI methods are not able to distinguish between different infection-causing microorganisms. Microorganisms have diverse metabolite profiles that are distinct from mammalian metabolites [76]. This makes MR spectroscopy a suitable method for determining the etiology of an infection.

MRS chemotypes living microbial and mammalian cells by providing information on their chemical constituents rapidly and simultaneously. Studies on cell suspensions have shown that even closely related bacteria and fungi could be distinguished when MR spectra were analyzed by pattern recognition techniques [77,78]. Metabolites identified by MRS in cell cultures were also found in body fluids and biopsies from infective tissue [68,79–81]. If typical marker metabolites are present infection-causing microorganisms can be identified or at least classified without isolation and cultivation. In cases where spectroscopic patterns are similar to those from other pathologies, such as the presence of large concentrations of lipids and lactate in *Staphylococcus aureus* or *Streptococcus milleri* abscesses as well as necrotic GBMs, diagnostic "marker" metabolites can be masked. Analysis of MR spectra by statistical classification methods is still powerful enough to distinguish between such similar spectroscopic patterns [68,82,83].

In vivo MRS has been reported to distinguish the broad group of pyogenic abscesses from malignant gliomas and tuberculoma non-invasively [8,48,75,84–90]. A selection of *in vivo* MR spectra from brain abscesses is shown in Figure 2. While highly necrotic and cystic tumors and pyogenic abscesses contain both, large amounts of lipids and lactate, other organic acids like acetate and succinate have been identified in cerebral abscesses in humans and utilized as bacterial "marker metabolites" for non-invasive diagnosis by MRS. Diverse profiles of organic acids are mainly characteristic for hetero-fermentative bacteria [76]. In addition, elevated concentrations of amino acids have been found in pyogenic abscesses [86,88]. This could not always be confirmed, as MRS of abscesses caused by microaerophilic bacteria like *S. milleri* and *S. aureus* did not consistently show elevated resonances from amino acids [8,68]. A remaining diagnostic problem is the differentiation between abscesses caused by exclusively

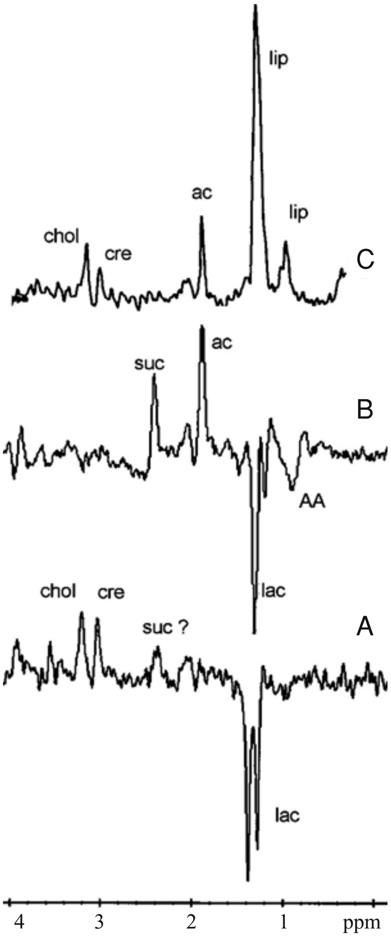

Fig. 2. MR spectra of bacterial abscesses with different etiological composition. Spectra were acquired from an 8 cm^3 VOI placed in the center of the lesion on 1.5 T human MR scanners (TR/TE = 3000/135). Bacteria causing the infections were: (A) *Streptococcus milleri*, (B) *Streptococcus milleri* and *Bacteroides fragilis* (same patient as in Figure 1), and (C) *Staphylococcus aureus, Proteus mirabilis*, and *Escherichia coli*.

Table 1: Choline to creatine ratio determined by integration of the resonances at 3.2 and 3.0 ppm, respectively. Ratios were determined for cystic GBMs, abscesses with growth of *Streptococcus aureus* and sterile abscesses

	Cases	Mean ± SD	Range of choline:creatine ratio
Cystic GBM	11	1.8 ± 0.8	0.4–4.2
S. aureus abscess	9	0.9 ± 0.4	0–1.4
Sterile pus	5	0.2 ± 0.1	0–0.4

microaerophilic bacteria, sterile cysts, and cystic glioma. MR spectra of these lesions contain only resonances from lipids, lactate, and choline containing compounds. Attempts were made to distinguish between these groups based on increased choline levels in gliomas [8]. As Table 1 indicates, substantial overlap exists between the choline to creatine ratio in these lesions. However, statistical analysis of MRS from animal models has indicated that classification is feasible [68].

MR spectroscopy was also able to identify a characteristic pattern for parasitic infections (cysticercus and hydatid cysts) [91,92] as well as yeast infection (cryptococcoma) [56,80]. Relatively non-specific MR spectra were acquired from cerebral aspergillosis [53], nocardidosis [48], and tuberculomas [75,93].

Treatment of brain abscesses was monitored in animal models as well as humans. It was noticed that characteristic metabolites of hetero-fermentative bacteria like acetate and succinate disappeared completely [8,85,94]. Only lactate remained in these cases. These results indicate that the spectral specificity is only valid for untreated abscesses or soon after the start of treatment and that success of antibiotic treatment can be monitored by MRS.

In general, MR spectra acquired with long echo times are most informative as potentially masking intense resonances of lipids are suppressed and phase modulation due to J-coupling supports resonance assignment (lactate, amino acid residues). Unequivocal resonance assignment is currently not possible *in vivo*. First attempts to utilize localized *in vivo* ^{1}H, ^{1}H-COSY spectra for clinical diagnosis are promising and might further improve diagnostic accuracy when applied to abscesses [33,34]. It remains to be seen if the currently unsuitably long acquisition times can be reduced.

Considering the diversity of microorganisms causing brain lesions and the sparseness of cases for some of them, more MRS data are required to evaluate the whole potential of MR spectroscopy and to suggest robust strategies for its application to *in vivo* diagnosis. Based on small numbers, distinction between abscess causing microorganisms seems to be feasible [8,86,87]. This was confirmed for animal models in which a relatively large number of reproducible lesions can be evaluated by MRS [68,80].

Data Analysis

Diagnosis in radiological practice is based on interpretation of images by individuals. Using various MRI methods, this is feasible by following flow charts in the decision making process. Although the diagnostic value of MRS is established, it is little used for medical diagnosis, since interpretation of spectra is complex and few clinicians are trained to use this method. Diagnosis of abscesses is relatively easy in the presence of anaerobe microorganisms that produce unique “marker” metabolites like acetate or succinate [6,84,86,90]. However, focal infections caused by other microorganisms may result in MR spectra that appear similar to those acquired from other pathologies [8,68,86].

Metabolite assignment and quantification can be assisted by utilization of fitting routines like LCModel and other programs [32,95,96]. These semi-automated spectral evaluation tools have the disadvantage that some prior knowledge is required for data fitting, as only metabolites that are in the base set of LCModel can be quantified. Although, the latest versions of LCModel contain a relatively large set of metabolites or can be extended by additional model metabolites [32,97], this would always require prior knowledge and the accumulation of MR spectra from metabolites that are expected to be of value for the diagnosis of infections. The list of such metabolites could include organic acids like acetate, succinate, butyrate, propionate, and carbohydrates/polyols like trehalose, and mannitol. It remains to be seen if fitting routines are still reliable if extended by such a large number of metabolites.

The project International Network for Pattern Recognition of Tumours Using Magnetic Resonance (INTERPRET) aims to develop a decision support system that automates the analysis of multimodal MR data (MRI and MRS) for clinical diagnosis [98,99]. The objective of this multicenter study is the classification of brain tumors. It was demonstrated that, based on a large set of MR spectra for training and various pathologies, fully automated processing and analysis of test spectra by pattern recognition techniques was relatively robust and accurate [98].

Similarly, Poptani *et al.* were able to distinguish between tumors and non-neoplastic disorders using neural networks for the classification of MR spectra [100]. However, neural networks tend to be over-optimistic in cases of relatively small data sets.

A more robust approach was successfully used for the identification of microorganisms and classification of brain abscesses in animal models [8,68,77]. A statistical classification strategy (SCS) of MR spectra that consisted of: (1) automated processing of the spectra, (2) feature reduction by a genetic algorithm-based optimal region selection [101] and (3) the development of a set of linear discriminant analysis-based classifiers was robust and highly accurate. The validation of a classification system containing five classes of closely related pathogens resulted in less than 2% misclassifications [77]. As SCS was successful for the diagnosis of abscess animal models [68] and *in vivo* MRS data to classify human diseases, this seems to be a promising approach for the development of a multiclass classification system for the non-invasive diagnosis of focal brain infections that does not rely on the operator's ability to interpret MRS data. The limiting factor is the sparseness of data to make such a system robust.

Summary

A definitive diagnosis of infective lesions is still typically established by culture of bacteria from invasively obtained samples. Further reduction of mortality from brain abscesses requires more rapid, accurate, and safe diagnostic techniques. It is currently possible with conventional MRI to distinguish infective lesions from a broad range of other pathologies that are indistinguishable by other radiological modalities. Conventional MRI methods of typical abscesses result in hypointense lesions on T_1-weighted images, hyperintense lesions on T_2-weighted images, and ring enhancement in T_1-weighted images after administration of Gd-based contrast agents. The remaining indistinguishable pathologies (necrotic and cystic tumors, tumorfactive multiple sclerosis, and other demyelinating lesions) can be distinguished from infective lesions with relatively high probability by using DWI, PWI, MT MRI combined with MRS. DWI results typically in a reduction of ADCs in abscesses. However, variability in viscosity of pus in abscesses causes a large variability of ADCs, resulting in unchanged or even increased ADCs for some cases. MRS is the most promising method to distinguish between different etiologies of brain infections due to its ability to identify bacterial "marker" metabolites. MRS has also demonstrated its potential to assess the success of treatment. With increasing computerized data analysis and statistical data interpretation, an objective, automated data interpretation is feasible for clinical diagnosis. However, MRS fails if lesions are small (<1 mm) or if only a small cohort of cases is available. Animal models can overcome the limitations of small case numbers. Correlation between models and clinical cases has been successfully demonstrated.

Glossary of Terms

Abscess—Focal infection that consists of an abscess capsule, containing fibrous material and chronic inflammation cells; and a central cavity filled with pus.

Focal infection—Infection that is results in the formation of lesions. Can be caused by bacteria, fungi, parasites, or viruses.

Glioblastoma Multiforme—Highly malignant tumor with a low overall survival time for most patients. They are histologically characterized by a dense cellularity, high endothelial proliferation, and often the presence of focal tissue necrosis. These tumors are can occur in a cystic form.

Pus—Content of an infective lesion. It consists of dead and dying polymorphous cells (leucocytes), living and dead microorganisms, tissue debris, and other components of inflammation (edema fluid and fibrin).

Introduction

Proton magnetic resonance spectroscopy (^{1}H MRS) provides detailed information on cellular metabolites in whole cells and tissues enabling a non-invasive assessment of the chemical composition of these samples and the changes that occur with a disease process. As such, ^{1}H MRS can be used as an adjunct method for the pathological staging of human biopsy tissues [1–3]. Single pulse or one-dimensional (1D) proton spectra are rich with information, containing overlapping resonances from a number of mobile intracellular and extracellular metabolites and present in millimolar and submillimolar quantities. As a result of this overlap, information from metabolically important or potentially diagnostic resonances can be obscured, affecting both peak assignment and quantitative estimation of metabolite levels. One method of overcoming this problem has been the development and application of two-dimensional (2D) magnetic resonance (MR) spectroscopic methods to deliver additional chemical information than that available from 1D spectra.

2D magnetic resonance spectroscopy (MRS), from its initial proposal by Jeener in 1971 (reprinted in [4]), and first applications in the late 1970s [5] has developed into a major tool in organic and inorganic chemistry for spectral assignment and structural determination [6,7]. 2D spectroscopy relies on the collection of multiple free induction decays (FIDs) with the systematic incrementation of a delay time separating one or more pulses in the time domain of a pulse sequence. This results in a variable time-dependent evolution of spin interactions during this delay, thus effectively encoding information in a second frequency domain. 2D Fourier transformation is used to convert the 2D time-domain data into two frequency domains, which is often displayed as a contour plot with two frequency axes representing the primary spin properties of interest (e.g. chemical shift, J-coupling) and cross peaks joining regions of the spectra where spin interactions have occurred. A number of excellent review articles and textbooks have been published on 2D MRS, and the interested reader is referred to them for a detailed theoretical framework and practical information on pulse sequence design and implementation [6–11].

The most common 2D MR experiment used on biological specimens to date has been homonuclear ^{1}H–^{1}H magnitude mode correlated spectroscopy (MM-COSY). The additional chemical information obtained from the COSY experiment arises from protons that are linked or coupled through covalent bonds in a molecule, appearing in the 2D spectra as a pair of intersected resonant frequencies or cross peaks [6]. In principle, however, any homonuclear or heteronuclear 2D MRS experiment can be applied to biological samples, limited only by the imagination of the investigators. In practice, however, there are a number of limitations that arise when dealing with samples of biological material, including the stability of cells or tissues, restricted metabolite motion leading to the presence of multiple and short T_2 relaxation values, and the detection of low concentration metabolites. There are also issues associated with the low natural abundance and sensitivity of some nuclei [12].

In this chapter, we will address the practical issues associated with sample preparation, data acquisition, data processing, and interpretation of 2D spectra, concentrating primarily on the application of 2D spectroscopy to the

study of human biopsy material. We will place the subject in perspective by briefly reviewing the literature, followed by a presentation of some theoretical aspects relevant to 2D spectroscopy of tissues, and then discuss the technical aspects of sample preparation, 2D data acquisition, and strategies for data processing.

Application of 2D NMR Spectroscopy to Cells and Tissues

Although the technique of 2D NMR spectroscopy was first introduced in the late 1970s, it was not applied to the study of biological materials until the 1980s. The first published study used MM-COSY to identify fatty acyl chain resonances in a packed suspension of rat mammary adenocarcinoma cells [13]. It was soon recognized that the fatty acyl chains and head groups, that constituted the most intense cross peaks in many 2D spectra, arose from mobile lipid resonances, predominantly neutral lipids such as triglycerides and cholesteryl esters [14–16]. However, a number of other cross peaks were also observed in 2D spectra of cells [14–16]. The assignment of these cross peaks in 2D spectra were facilitated by the applications of techniques such as T_2 filters to selectively observe resonances with long T_2 [17], and 2D J-resolved spectra to assist in resonance assignment [18]. It was recognized that in biological samples containing metabolites with a range of T_2 relaxation values, the size of the acquisition domains and the window functions applied in processing could have dramatic effects on cross peak appearance and structure in COSY spectra [12]. As a result of these advances, over 40 cross peaks were identified in COSY spectra from intracellular metabolites. A comprehensive table of resonance assignments of lipids, amino acids, and sugars present in colorectal cancer cells was published in 1992 [19], and a similar table showing resonances observed in thyroid tissue biopsies [20], is presented in Table 1.

Around the same time, COSY and 2D J-spectroscopy were applied to investigate animal tissues such as rat brain *ex vivo* [18,21,22]. One of these studies showed one of the first 2D COSY spectra on dead rat brain *in situ* [18], thus demonstrating the feasibility for the later development of 2D MRS *in vivo* [23–27]. In another study, lactate COSY cross peak intensities were shown to be linearly correlated with lactate concentration in muscle thus providing a potential method of estimating relative metabolite concentrations [28]. The first application of total correlation spectroscopy (TOCSY) on frog muscle was published in 1990 [28]. Since these initial studies, 2D spectroscopy has become a standard spectroscopic tool for the study of cells and animal tissues, including the activation of immune cells [29–32], detection of changes associated with tumor development and progression [33,34], and the study of the actions of antitumor drugs on cultured cancer cell lines [35–37].

The first application of 2D COSY to human tissue was on a human ovarian biopsy specimen [38]. An initial study demonstrated that *ex vivo* 2D spectroscopy might be useful in discriminating the pathology of human cervical punch biopsies [39]. This was followed by the first major clinical study using 1D and 2D spectroscopy on 159 cervical biopsy specimens that showed consistently increased lipid cross peaks in malignant relative to premalignant specimens [40]. Subsequent studies were published demonstrating the usefulness of 2D COSY as an adjunct to 1D MRS and histopathology on brain tumors [41,42], colon adenomas and carcinomas [43], draining lymph nodes [44], and in samples from ovarian cancer [45] and thyroid cancer [20]. TOCSY and 2D J-resolved spectra have also been used to study smooth muscle tumors [46], myosarcomas [47], and liposarcomas [48]. The use of ^{1}H MRS on human biopsies as an adjunct to histopathology is discussed in detail elsewhere in this issue and in a number of review articles [1,2,49].

There has recently been a renaissance in 2D spectroscopy of human and animal tissues because of two innovations, reviewed elsewhere in this issue: the application of magic angle spinning (MAS) and the development of techniques for obtaining *in vivo* 2D spectra. *In vivo* 2D spectroscopy has the potential to permit the detailed examination of metabolites of diagnostic or metabolic interest *in situ* [23–25], and may extend 2D methods into the realm of true non-invasive detection of disease. MAS has allowed MR spectra of biopsy tissue to be obtained with extremely high resolution. Of particular relevance to this chapter is the application of 2D MAS experiments for high-resolution resonance assignment in animal and human tissues. MAS analogs of the homonuclear COSY, TOCSY, and J-resolved experiments have been developed for the evaluation of metabolite profiles characteristic of human disease in breast [50,51], kidney [52] and prostate tumors [53], liposarcomas [48], and draining lymph nodes [54]. Further, MAS analogs of the heteronuclear ^{1}H–^{13}C heteronuclear multiple-quantum correlation (HMQC) and heteronuclear single-quantum correlation (HSQC) experiments have been employed to assist in resonance assignment in human tissues and in animal model studies [52,55–58].

2D MR Spectroscopy

The major advantage of 2D MRS is the separation of resonances that overlap in 1D spectra. 2D spectroscopy collects data in two time domains, t_1 and t_2, which can be converted to two frequency domains, F_1 and F_2, by double Fourier transformation. The t_2 is the direct or acquisition dimension that consists of the FIDs collected in the 2D experiment, and t_1 is the orthogonal, or indirect, dimension defined by the number of FIDs acquired in the 2D

Table 1: Assignment of major cross peaks in 2D ^1H–^1H COSY MR spectra of thyroid biopsy tissue*

Molecules	Abbreviation	Coupling partners (bold face)	Cross peak coordination (ppm)
Lipid			
Fatty acyl chains	A	$-(CH_2)_n-C\mathbf{H}_2-C\mathbf{H}_3$	1.27, 0.87

experiment. The 2D pulse sequence is often divided into four time periods: the preparation, evolution, mixing, and detection periods (Figure 1). The preparation period consists of a delay time during which equilibrium is attained and/or solvent suppression is performed, followed by a radio frequency (rf) pulse or series of pulses to prepare transverse magnetization. The evolution period consists of a variable delay time $t_1 + \Delta t_1$ during which magnetization evolves. The mixing period includes at least one rf pulse or a series of pulses and delays, to induce mixing of states and magnetization coherence transfer. The detection period is the time of FID acquisition, t_2. The indirect dimension is sampled by systematically incrementing the delay time in the evolution period, thus modulating the available magnetization during the mixing period. The size of the increment, or sampling period, in the t_1 dimension is inversely proportional to the spectral width in F_1 [59].

Choice of Pulse Sequence

In principle, any 2D pulse sequence can be applied to studies of human biopsy tissue, within the constraints defined by the stability of the sample. These time constraints make heteronuclear experiments more difficult to perform, especially for nuclei of low natural abundance. Many of these problems have been overcome using gradient-enhanced techniques with inverse detection and ^1H–^{13}C HMQC and HSQC MAS experiments have been

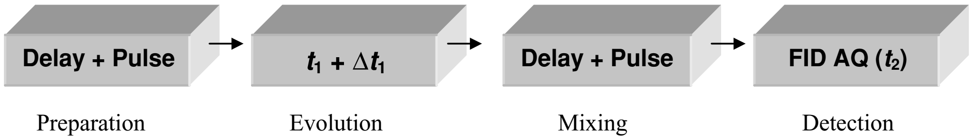

Fig. 1. The four basic periods of a 2D experiment.

reported for resonance assignment in human and rat tissues [52,55–58]. To date, however, the majority of 2D studies have been performed using ^{1}H–^{1}H homonuclear 2D spectroscopy, with COSY, 2D J-resolved and TOCSY experiments being by far the most common. Different and complementary information is available from these experiments, such that they may be usefully applied alone or in tandem to tissues of different origins.

The COSY sequence is the simplest and one of the most useful 2D experiments. The basic MM-COSY pulse sequence (Figure 2A) consists of two 90° pulses, the first to create magnetization in the transverse plane and the second to mix spin states, transferring coherence between scalar coupled spins. A variable delay $t_1 + \Delta t_1$ separating these pulses is incremented systematically during the evolution time and the FID is acquired during the detection time, t_2. After Fourier transformation the 2D spectrum consists of a diagonal representing spins that did not exchange magnetization during the mixing period and cross peaks or off-diagonal peaks for nuclei exchanging magnetization through scalar coupling. Since MM-COSY spectra are collected with no phase discrimination in F_1, a magnitude calculation must be performed after Fourier transformation.

Phase-sensitive double-quantum filtered COSY (PS DQF-COSY, Figure 2B) is an analog of the COSY experiment. The data are collected using time-proportional phase incrementation (TPPI) [60], in which the phase of the first pulse is incremented by 90° in successive FIDs resulting in phase discrimination in F_1. This obviates the need for the MM calculation, leading to improved apparent spectral resolution. However, the phase discrimination in the t_1 dimension means that twice as many FIDs need to be collected to achieve the same resolution. The signal to noise (S/N) is unchanged because S/N is proportional to the product of the number of transients (NS) and the number of FIDs acquired [6]. Thus, the total acquisition time (AQ) can remain constant by reducing the equivalent number of scans by a factor of two.

In the DQF pulse sequence, the first and second pulses act as in the MM-COSY. The third pulse in the DQF-COSY pulse sequence converts double-quantum magnetization into observable single-quantum magnetization, with phase cycling or gradients used to cancel unwanted single- and multiple-quantum magnetizations. This results in the diagonal signals of uncoupled nuclei, arising from single-quantum magnetization, being severely reduced as well as the conversion of the dispersive diagonal peaks into pure antiphase absorptive signals. This is useful for biological samples, since cross peaks resulting from the coupling of nuclei with similar chemical shift appearing near the diagonal can be resolved [61].

The 2D J-resolved sequence (Figure 2C) consists of a 90° preparation pulse, followed by the incremented delay

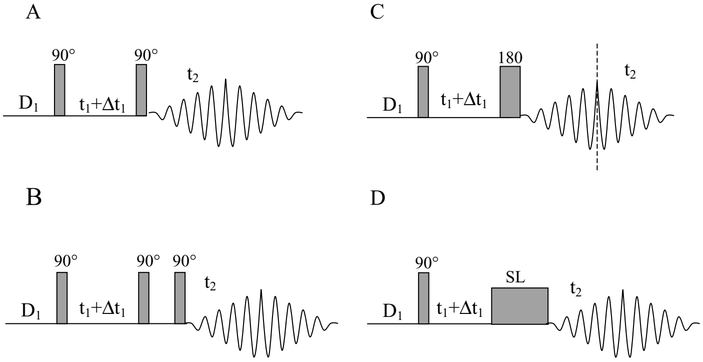

Fig. 2. Four basic 2D homonuclear pulse sequences routinely used in the study of human tissues. (A) ^{1}H–^{1}H MM-COSY, (B) ^{1}H–^{1}H DQF-PS COSY, (C) ^{1}H–^{1}H 2D J-resolved, and (D) ^{1}H–^{1}H TOCSY.

time and a 180° mixing pulse. The 180° pulse reverses linear spin interactions, such as chemical shift, such that at time $2(t_1 + \Delta t_1)$, chemical shift is refocused, leaving only interactions from J coupling in t_1. This results in a 2D spectrum with chemical shift on the F_2 axis and J coupling only on the F_1 axis. J-resolved spectroscopy has proven to be valuable for resonance assignment, especially in regions of the spectrum with substantial overlap.

One of the more useful methods in the 2D spectroscopic arsenal is the TOCSY (Figure 2D). In the TOCSY experiment, the mixing pulse is replaced with a spin lock field or series of pulses, often an MLEV-17 pulse train [62]. This allows coherence transfer between all coupled spins simultaneously, which ideally gives rise to cross peaks between all spins in a spin system. One advantage to the TOCSY experiment is that the coherence transfer results from in phase rather than antiphase magnetization, leading to in phase cross peaks that are not subject to cross peak cancelation.

Sample Preparation

A general harvest procedure that we have found acceptable is to collect unfixed, surgically removed tissue specimens from the operating theatre. To prevent sample decomposition, these specimens are placed immediately into vials containing phosphate-buffered saline in D_2O (PBS/D_2O), snap frozen in liquid nitrogen and stored at −70 °C. Samples can generally be stored this way for several weeks, without serious deterioration. Samples for MR experiments are cut frozen into tissue plugs of wet weight 20–50 mg and washed in PBS/D_2O, although this washing may lead to depletion or removal of certain metabolites [63]. Positioning of the sample in a standard NMR tube can be performed by placing the tissue on top of a glass susceptibility plug in a susceptibility-matched MR tube, or by suspending the tissue either in buffer or on the surface of glass wool plug. The NMR tube need not be filled with tissue to obtain reasonable spectra. Smaller cylindrically shaped samples are easier to shim and the presence of deuterated buffer is advantageous for locking purposes. Sample preparation for MAS is dealt with elsewhere in this issue.

Data Acquisition

A 2D data set consists of a series of FIDs, which are acquired and stored consecutively in a file as a 2D matrix of points. A number of operator controlled factors affect the total experiment time of the 2D data set: most notably the total repetition time, which is pulse sequence dependent, the NS collected per FID in the t_2 dimension, including dummy scans (DS) performed to put the spin system in a steady state before data accumulation, and number of experiments (NE), the number of FIDs to be collected in the t_1 dimension. The repetition time includes parameters such as the relaxation/equilibrium delay, the incrementation delay during the evolution period, and the t_2 AQ.

The relaxation delay in the preparation period is dependent on the T_1 relaxation values of the sample. Ideally, five times the longest T_1 should be used to ensure that all spins are fully relaxed before the experiment begins. In practice, a 3-h time constraint allows only about 8000 transients (for example 250 FIDs of 32 transients) to be acquired before viability drops below an acceptable level. This requires acquisition parameters that are less than ideal: a repetition time of about 1.4 s is an absolute minimum for establishing an optimal steady-state magnetization and avoiding spurious coherences and instabilities due to the presence of residual transverse magnetization before the excitation pulse [12]. In general, the AQ should be at least 3 T_2 and the repetition time have a minimum value of 1.3 T_1. For lipid resonances, T_2 and T_1 relaxation values in cells have been reported to be in the range of 120–300 and 200–600 ms, respectively [41,48,64–66].

The transmitter offsets for both t_1 and t_2 time domains should be set to the center of the spectrum. For ^1H–^1H spectra, the transmitter offsets can conveniently be set to the water frequency, which lies approximately in the center of the spectrum with spectral widths, sw_1 and sw_2 equal to 10 ppm. The size of the time increment, Δt_1, is related to the spectral width, for MM-COSY Δt_1 is equal to $1/sw_1$, and for PS-COSY to $0.5/sw_1$. The NS to be collected for each FID is generally a multiple of eight if full phase cycling is used. Gradient-assisted sequences, such as the G-COSY [67–69] can be used to reduce the number of scans in the phase cycle, but in small biopsy specimens of 20–40 mg wet weight, S/N is sufficiently limited such that often 32 or more scans must be collected to obtain 2D spectra with reasonable S/N ratios.

One major consideration in the acquisition of 2D spectra of human tissues is the time allocated to collect experimental data. This is important for two reasons, the first is that metabolite levels can change over time due to sample degradation, especially if the data are collected at temperatures above ambient. Neutral amino acids resonances from proteolytic breakdown will often appear as sharp peaks on the downfield side of the methyl resonance in 1D spectra [63]. In the case where the total experiment time is sufficiently long, the contribution of these resonances to the 2D cross peaks will almost certainly be variable over time. Secondly, it may be necessary or desirable to have histopathology performed on the same piece of tissue that was used to acquire the spectrum, in the case where only small pieces of tissue are available, or where direct comparison of spectral properties and histological diagnosis is required. This is a more stringent condition, since the tissue must remain in good enough shape for a pathologist to make a reasonable diagnosis. In cervical biopsy tissue, we found that colposcopically obtained punch biopsies kept at 37 °C for 1.5 h, remained suitable for histopathological analysis. Although these parameters may vary for different tissue types, for punch biopsy sized tissue (5–10 mg) this is not enough time for anything but the detection and assignment of major metabolite cross peaks.

The limited time available for data collection means that acquisition parameters must be established to achieve an optimum S/N ratio in the limited time available. In practice, this generally means restricting the number of FIDs collected in t_1, balancing the desired or necessary spectral resolution against S/N and sample viability [12]. For equal resolution in F_1 and F_2 in COSY or TOCSY spectra, a square 2D data set of complex data points must be collected (e.g. 512 × 2K for MM; 1024 × 2K for PS mode). In small biopsy specimens of 20–40 mg, a reasonable S/N ratio can be obtained in a total experiment time of 2–3 h. For COSY and TOCSY spectra, the collection of 200 FIDs of 32 transients will give reasonable S/N and resolution for most specimens in about 3 h. Recall that for PS data, the phase discrimination in F_1 dictates that twice the number of FIDs be collected, with half the number of scans for equivalent resolution and S/N [6]. For ^{1}H–^{1}H J-resolved spectra, where the detection of scalar coupling requires a spectral width in F_1 on the order of about 100 Hz, the number of FIDs accumulated in t_1 can be correspondingly reduced to 100–150 [55,70]. For heteronuclear MAS experiments, t_1 domains of around 200 FIDs have frequently been used to obtain reasonable resolution in human and animal tissues [55–57].

Data Processing

2D data processing converts a 2D time-domain data set to a 2D frequency domain spectrum. The general steps involved are zero filling, apodization by multiplication with a window function, and Fourier transformation. This is followed by phase correction for data collected in PS mode or magnitude calculation for MM collection. Zero filling is the procedure of supplementing the time-domain data points with a string of data points with zero amplitude prior to Fourier transformation to improve digital resolution [6]. In 2D MRS, zero filling is also used when the collected matrix of data points is not square or incomplete. In general, time constraints dictate that the number of increments collected in the t_1 domain be as few as possible. As a result zero filling of at least one level is recommended to improve resolution in t_1 [6].

Apodization and the Use of Window Functions

Since a wide range of T_2 relaxation values are encountered in biological samples, additional considerations and flexibility are required for processing 2D spectra. Different window functions may be applied to the data set to extract relevant information from different peaks [12]. A window function is a time-dependent analytical mathematical function that shapes or filters the signal envelope, providing apodization to avoid truncation artifacts created by zero filling, or when acquisition is terminated before signal has fully decayed. Window functions are also used to maximize S/N and resolution, minimize line widths or to convert the frequency domain lineshape into a more desirable form [6,7,71]. Windowing is achieved by point-by-point multiplication of the window function with each data point of the FID in the time domain, which results in a convolution of the window function with the data set in the frequency domain.

In coherence transfer 2D spectra, where the desired information is often contained in an echo not centered at the beginning of the time domain, window functions are chosen that have the form of a pseudoecho, with small initial values, peaking later in the time domain and decaying smoothly to zero. Three commonly used window functions for 2D data processing are the Lorentzian–Gaussian (LG), sine-bell (SB), and shifted sine-bell (SSB) window functions.

The unshifted SB function begins at an initial value of zero rising to a normalized value of 1 halfway through the data set (at the time point $t_i = t_m =$ AQ/2), decaying smoothly to zero in both the t_1 and t_2 time domains. The unshifted SB function emphasizes sine dependent cross peaks relative to cosine dependent diagonal peaks and removes broad wings (dispersive components) from MM lineshapes. SB window functions optimize the presentation of high-resolution cross peaks from spins with long relaxation times, but spins with shorter relaxation times, those with $T_2 <$ AQ may exhibit substantial signal loss [6,12]. The SSB function is similar to the sine and can be used on samples with $T_2 >$ AQ. The initial value of the SSB function is not zero but (π/n), with $n \geq 2$. However, the SSB is not as effective at canceling out dispersive wings in MM spectra [6]. The application of SB windows to a complete symmetrical 2D data set can result in a 2D spectrum in which only cross peaks from a number of free amino acids and low molecular weight metabolites appear.

The LG window function is commonly used as a window function in t_2. The LG function has two adjustable parameters, which offer increased flexibility in the position and shape of the window function within the time domain and allows optimum detection of short T_2 species such as lipids. The LG function is controlled by two parameters: a Lorentzian broadening (LB), expressed as a negative number in Hz, and a Gaussian lineshape transformation fraction (GB). GB is a decimal fraction, which positions the LG maximum at GB × AQ, scaled such that $\mathrm{LG}_{\max} = 1$. The position of the LG window is controlled by adjusting GB, while adjustment of the LB parameter controls the initial and final values and width of the window function in the time domain, but not independently of GB.

The detection of compounds with short T_2 requires that the length of the time domains be reduced before performing the 2D F T, which can be achieved either by applying the LG function with the maximum shifted to a shorter time, or by reducing the number of data points used for processing and using symmetrical window functions such as the SB. There is no particular advantage to the LG over the SB window if the maximum in the SB window is positioned by adjusting the number of time-domain points. In fact, reduction of the number of t_1 points is often the condition set by sample viability and can be achieved by reducing the number of FIDs acquired or used in processing. If short T_2 species are of most interest, the efficiency of data acquisition can be significantly improved by acquiring fewer FIDs with correspondingly more transients per t_1 value. The analysis of cross peaks from both long and short T_2 species in a single data set can only be performed by acquiring conventional data sets with long AQs and performing several transforms with processing time domains and window functions optimized for the T_2 and J values of the cross peak of interest.

Quantitation

Although 2D spectroscopy can reveal numerous differences in the metabolite profiles in normal and diseased tissues, absolute quantitation of changes in metabolite levels, as in all forms of MR, can prove to be problematic, and must be performed with care. One method of quantifying 2D coherence transfer (e.g. COSY and TOCSY) spectra is by integrating the volume enclosed by a cross peak above the base plane (noise level) of the 2D spectra. However, there are a number of factors, besides the concentration of the species that influence both the appearance and the intensities of cross peaks in 2D spectra. These factors include the molecular weight and the T_2 relaxation value of the coupling partners, the MR pulse program being used and the chosen acquisition and processing parameters. In the case of COSY spectra, cross peak intensities can be further decreased due to cross peak cancelation arising from antiphase signal components [7,59]. Cross peak cancelation is more serious for resonances with short T_2 relaxation values, or small J-couplings since the degree of cancelation depends on the ratio of J/T_2. For COSY spectra, the problem is further complicated since the sum of the integrated area for any antiphase cross peak is zero. Therefore, any non-zero cross peak volumes have to be obtained either from spectra in which a MM calculation has been performed or from the sum of positive and negative antiphase components in PS spectra. TOCSY cross peaks appear as pure absorption mode, not antiphase, and hence and are not subject to problems arising from cross peak cancelation.

As a result, of these limitations it is difficult to compare absolute concentrations of two species in the same 2D spectrum, as well as difficult to estimate the concentrations relative to internal or external standards. However, if collected and processed under identical conditions, the same cross peaks from two different 2D spectra can be compared. Assuming that the experimental treatment does not change the T_2 of the cross peak of interest, it is possible to estimate the relative concentration from cross peak integrals.

It is worth noting that the volumes of cross peaks in COSY spectra have been shown to be linearly proportional to metabolite concentrations in standard solutions [28]. We have confirmed the linear dependence of cross peak volume on concentration in samples of mixed amino acids, and find that the linear relationship holds regardless of cross peak coupling partner (Watzl and Delikatny, unpublished data). Absolute concentration estimates of lipid and lipid metabolite concentrations in activating immune cells have been obtained by comparing metabolite cross peak volumes to those of paramagnetic-doped standards of similar T_2 and known concentrations [29,30]. Quantitation of heteronuclear correlation cross peaks has been reported in bacterial supernatants [72].

Factors Affecting Cross Peak Volumes

In order to improve the diagnostic potential of 2D ^{1}H MRS, it is necessary to understand the factors controlling the resolution and intensity of cross peaks in complex 2D spectra with multiple T_2 relaxation times [12]. As discussed above, window functions commonly used to improve the spectral resolution can selectively enhance cross peaks with different T_2 relaxation times [6,12]. Moreover, in unsymmetrized COSY spectra, significant asymmetries in cross peak intensities for methyl groups (for example those from alanine, lactate, and threonine) have been observed with peaks above the diagonal being generally more intense even when time domains and windows were equal. At higher fields this effect can be quite pronounced and can lead to substantial reduction in certain cross peaks upon symmetrization [12]. For this reason, quantitation should always be performed on unsymmetrized spectra.

In Figure 3, we present two MM-COSY 2D spectra of follicular thyroid tissue, acquired from the same sample, but processed using different parameters. In the t_2 dimension, 32 transients of 2048 data points were collected, and in the t_1 dimension, 512 FIDs (NE) were collected. The spectra were processed with a LG window in t_2 and a SB window function in t_1; an NE of either

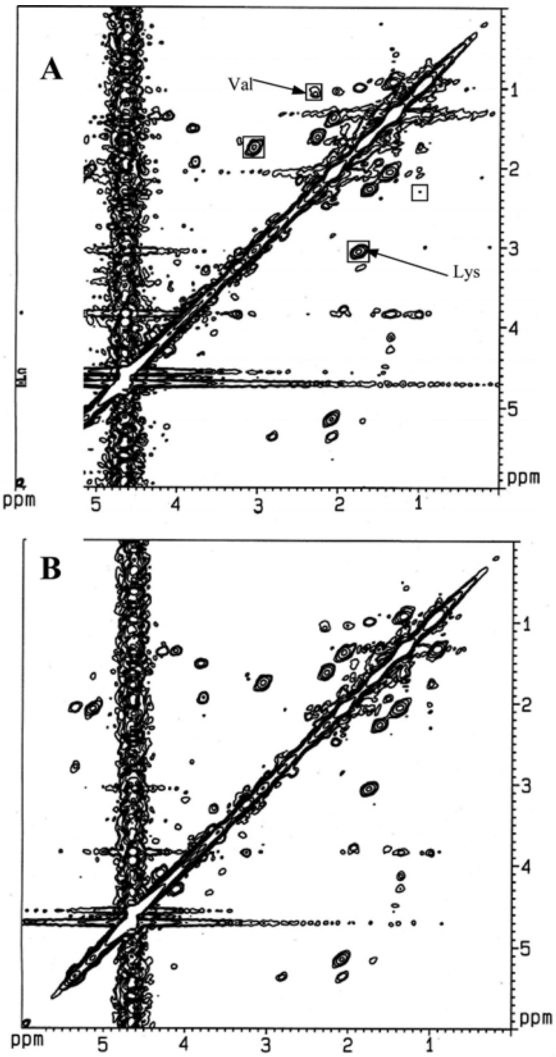

Fig. 3. Two-dimensional MM-COSY spectra of follicular thyroid tissue processed using (A) 200 and (B) 512 FIDs. In the t_2 domain, 2048 data points were collected and 512 FIDs consisting of 32 transients were collected in t_1. Data processing was performed with a sine-bell window applied in t_1 and a Lorentz-Gauss window in t_2 ($LB_2 = -30$, $GB_2 = 0.12$) before Fourier transformation. Cross peaks chosen for analysis are indicated with arrows.

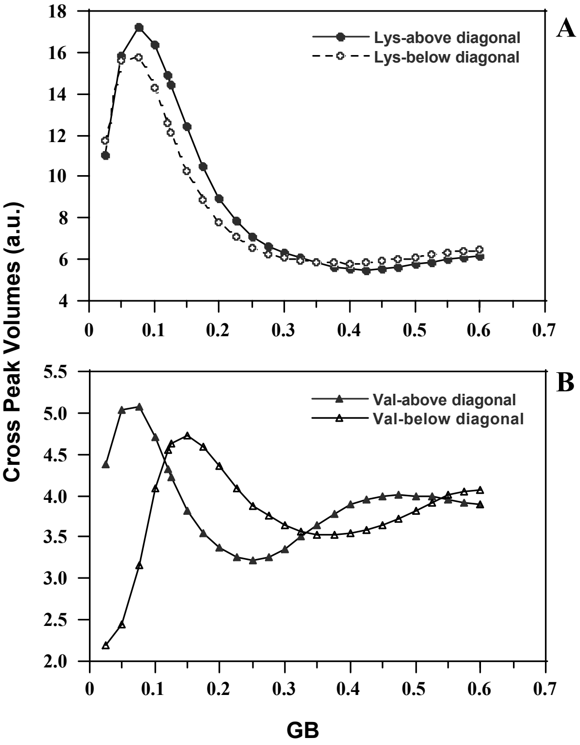

Fig. 4. Variation of (A) Lys $\mathbf{CH}_2$–$\mathbf{CH}_2$–NH_2 (1.67 and 3.00 ppm) and (B) Val $\mathbf{CH}_3$–$\mathbf{CH}$ (1.01 and 2.28 ppm) cross peak volumes as a function of GB in the t_2 time domain in magnitude-mode COSY spectra of follicular thyroid tissue processed with 200 FIDs. A sine-bell window was applied in t_1 and a Lorentz-Gauss window in t_2.

200 or 512 FIDs was used to produce Figures 3A and 3B, respectively. The volumes of two sets of amino acid cross peaks were selected from this data set (Lys, from the CH_2–$\mathbf{CH}_2$–$\mathbf{CH}_2$–NH_3^+ coupling of lysine at 1.67 and 3.00 ppm, and Val, from the $(\mathbf{CH}_3)_2$–$\mathbf{CH}$–CH coupling of valine at 1.01 and 2.28 ppm; arrows in Figure 3A), and the integrated cross peak volumes on the top and bottom of the diagonal and plotted relative to systematic changes in the processing parameter GB. Figure 4 demonstrates that cross peak volumes from COSY spectra vary significantly as a function of GB. The volumes measured for the pair of symmetrically matched cross peaks on either side of the diagonal are very close in value throughout the profile for the Lys cross peak whereas for the Val pair, they are substantially different. In contrast, cross peak volume profiles generated by varying LB resulted in strict monotonic increases in cross peak volume regardless of cross peak chosen (Figure 5).

Volumes measured from cross peaks at the same chemical shifts in different spectra display similar variation with respect to processing parameters, regardless of

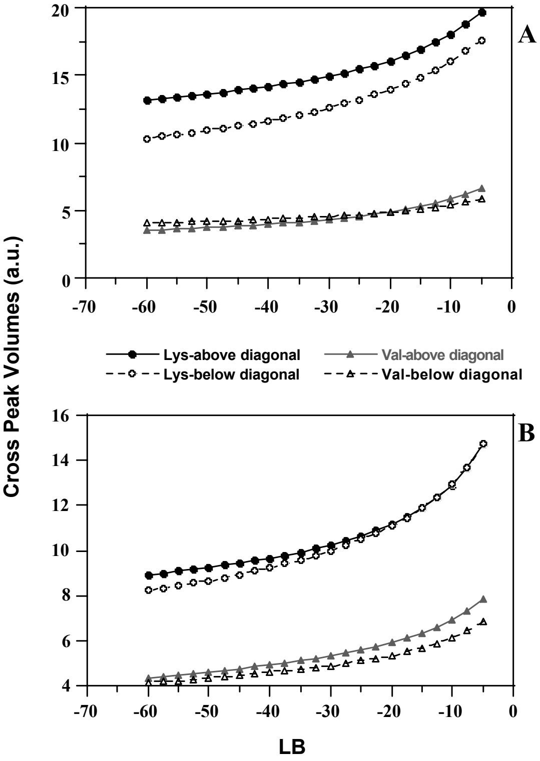

Fig. 5. Variation of cross peak volumes as a function of LB in the t_2 time domain in magnitude-mode COSY spectra of follicular thyroid tissue. A sine-bell window was applied in t_1 and a Lorentz-Gauss window in t_2. $GB_2 = 0.12$. Figure 5A and B were processed with 200 and 512 FIDs, respectively.

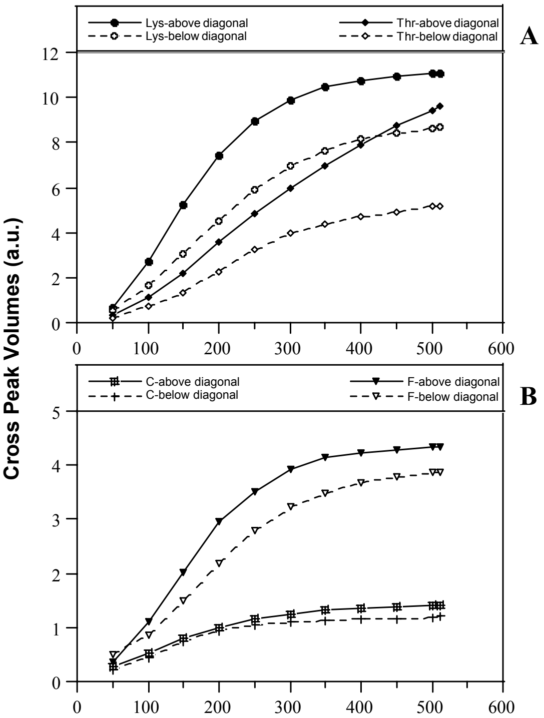

Fig. 6. Variation of cross peak volumes as a function of FIDs processed in the t_1 time domain in phase-sensitive double-quantum filtered COSY spectra of the malignant human colorectal cell line LIM 1215. A $\pi/4$ shifted sine-bell window was applied in t_1 and a Lorentzian–Gaussian window in t_2. $LB_2 = -30$, $GB_2 = 0.3$. (A) lysine and threonine, (B) F (–O–C(O)–$\mathbf{CH}_2$–$\mathbf{CH}_2$; 2.23, 1.57 ppm), and C (–CH_2–$\mathbf{CH}_2$–$\mathbf{CH}$=CH–; 2.00 and 5.31 ppm) resonances from mobile fatty acid chains.

whether the sample is a tissue specimen, cultured cells or a chemical standard [73]. Moreover, the comparison of cross peak volumes from either MM- or PS DQF-COSY spectra show similar patterns of oscillation, although they are dampened in samples with shorter T_2 relaxation values, such as tissue specimens. Similar analyses have not been performed on data obtained from other pulse sequences, e.g. TOCSY. However, this observation indicates that these processing dependent variations in cross peak volumes depend on the spin systems rather than the environment. As a general observation, cross peaks arising from symmetric AB and A_2B_2 spin systems show similar processing dependent volumes above and below the diagonal, whereas those from asymmetric A_2B, A_3B, or A_3B_2 show variation in cross peak volumes on either side of the diagonal [73].

Changing Parameters in t_1

The time constraints imposed by biological sample degradation restricts the number of t_1 increments collected during 2D experiments. The shortened t_1 time domain often leads to a restricted choice of window functions in t_1, and for COSY spectra the shifted or unshifted SB are most often used. Modulation of the phase shift of a SB window in t_1 leads to little variation in cross peak volumes for a constant number of FIDs processed (data not shown). However, for samples where large data sets have been collected, increasing the number of FIDs processed leads to increases in volumes for all cross peaks in all samples (Figure 6).

In summary, acquisition and processing parameters may be tailored to maximize the apparent S/N ratio of a cross peak and to affect the quality of 2D spectra. The disparity between volumes above and below the diagonal is controlled by the spin systems present in the sample. An understanding of the response of the spin systems and judicious choice of acquisition and processing windows allows an optimization of S/N ratio in cross peaks in 2D spectra, and allows better comparison of cross peaks between tissue samples of differing pathologies.

Concluding Remarks

2D MRS remains a powerful tool for the *in vivo* and *ex vivo* study of human cancer and other pathologies. The ability to separately identify numerous metabolites in human tissue non-invasively in a single experiment, allows a high degree of metabolic profiling to be performed that can be correlated with various disease states. The ability to assess multiple parameters through different pulse sequences gives 2D MRS extreme flexibility in experimental design. The limitations imposed by the time constraints inherent in dealing with tissue samples can be dealt with through careful experimental practice and attention to acquisition and processing details. The linking of modern 2D MR pulsed spectroscopic techniques with sophisticated technologies, such as MAS and *in vivo* spectroscopy, addressed elsewhere in this issue, hold great promise for the unraveling of metabolic parameters associated with the onset and progression of human disease.

Correlation of Histopathology with Magnetic Resonance Spectroscopy of Human Biopsies

Introduction

The pathology of human tissue can be determined by magnetic resonance spectroscopy (MRS) but it was a controversial field for over 20 years. Now MRS on human biopsies identifies disease processes, neoplastic status, and prognostic variables with high accuracy. The MRS databases were compared with careful and specialized histology [1,2]. The MR method is fast, accurate, and robust and for most organs complements routine histopathological diagnosis. For some organs such as the thyroid and esophagus it can provide information not available using a light microscope. However, rigorous procedures and quality control are required to ensure this level of accuracy and are the basis of this chapter.

The reason the MRS method is so precise is that it monitors changes to cellular chemistry during the development and progression of a disease process. This is also the reason that it was controversial. Unless the pathology was undertaken with care there were discrepancies. An early experiment, undertaken in 1978, demonstrated that MRS could identify sequential alterations in cells before they manifested frank malignancy by light microscopy [3,4]. This was an exciting step forward but it also meant that correlation with both pathology and clinical outcome was essential. Twenty-five years on the MRS method is confirmed to show pathological categories which are not documented by light microscopy, due to the absence of architectural differences. The cells do, however, have a different chemical make-up consistent with clinical outcomes [5,6].

The basis of the MRS method for identifying tumor pathology is the increase in MR visible chemical species with the onset and the development of the disease. This was clearly seen in the first clinical study on human cervix biopsies [7]. Cancer of the uterine cervix was chosen for the first clinical ^{1}H MRS study as, histologically, the distinction between the presence and the absence of malignancy is made with a high level of accuracy. As seen in Figure 1, invasive specimens are characterized by an intense MR resonance at 1.33 ppm, primarily from the methylene protons of lipid acyl chains, with additional contributions from the methyl protons of lactate and threonine. There are also methyl, choline, and olefinic resonances at 0.90, 3.2, and 5.32 ppm, respectively (Table 1). The spectrum from human papilloma virus infected tissue (Figure 1B) lacks the intense resonance at 1.33 ppm. Other visible spectral differences include increases in the broad resonances between 3.4 and 4.2 ppm in the pre-invasive specimens compared with their invasive counterpart. It can be seen by comparing these three spectra that there is a gradual increase in the MR visible chemistry associated with the development of disease. In this study, the accuracy of the MRS method was 98% [8].

It is now established that the MRS-detectable chemical information present in the primary tumor is reporting on cellular chemistry associated with tumor development and progression, as well as cellular proliferation, immunosuppression, and metastasis. For a review see Mountford *et al.* [2].

Histopathology—Strengths and Limitations

Histopathology is the gold standard of the 20th century, providing diagnostic and prognostic information for human diseases. It is a very mature discipline that draws upon the experience of medical specialists who rely on visual pattern recognition in human tissues and cells using light microscopy. Its major limitation is the restrictive range of morphological changes that tissues express. The changes are often in a continuum and from this the pathologists are expected to identify patterns for individual diseases. These patterns often overlap making it necessary to make a subjective assessment.

Of importance to the development of MRS as a mature discipline are the sampling errors inherent at several levels in routine diagnostic services. Routine hospital pathology will often examine only one or two sections per sample of tissue. This is at least partly due to the time cost of examining multiple sections of tissue. A study of prostate biopsies by Swindle *et al.* [9] demonstrated that routine hospital histopathology (i.e. one or two slices) failed to

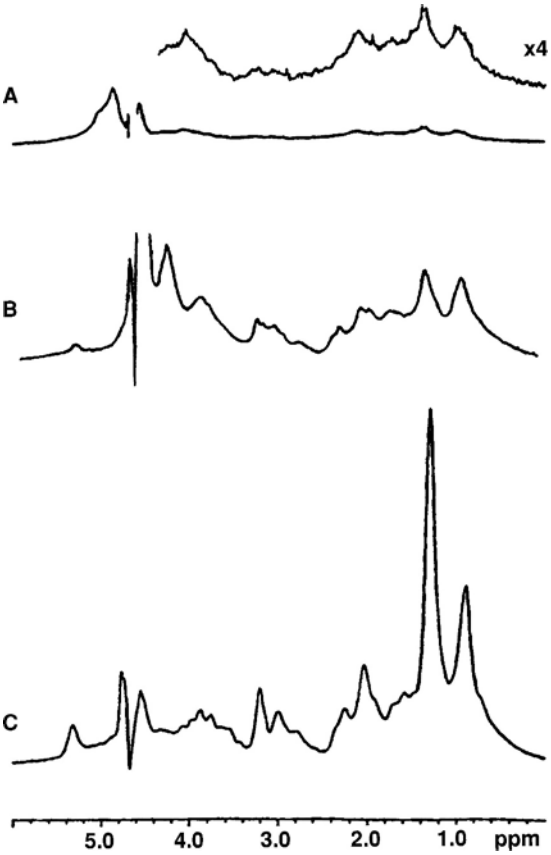

Fig. 1. ^{1}H MR spectra of cervical biopsy specimens. The histological assessment of each specimen is as follows: (A) Nonspecific chronic inflammatory disease. The inset shows the region 4.5–0 ppm with the vertical gain increased fourfold, NE = 400. (B) HPV infection but no significant dysplasia observed, 512 accumulations. (C) Cervical carcinoma, 40 accumulations. Spectra were recorded on a Bruker WM 400 (9.4 T) spectrometer at 37 °C. The water peak was suppressed by gated irradiation, sweep width 4000 Hz, acquisition time 1.024 s, and a line broadening of 3 Hz was applied in each case. *Source:* Reprinted from Magnetic Resonance in Medicine 1990;13:324–31. Mountford CE, Delikatny EJ, Dyne M, Holmes KT, Mackinnon WB, Ford R, Hunter JC, Truskett ID, Russell P. Uterine Cervical Punch Biopsy Specimens Can Be Analyzed by 1H MRS. With permission from Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc.

identify a number of cancers that have been detected by MRS. In order for the MRS method to achieve its potential and provide accuracies approaching 100% detailed non-routine histopathological analysis of the same piece of tissue examined by MRS is needed for correlation.

A good example of the need for serial sectioned histopathological analysis is seen in Figure 2. The spectra from breast ductal carcinoma *in situ* with and without microinvasion present are compared. Tissue sections of DCIS taken 100 μm apart are shown with microinvasion present and without microinvasion. The chemical activity seen in the MR spectrum of the cells with microinvasion is far greater. It should be noted that when both pathologies are present in a single specimen the most active chemical profile will normally be seen. The MRS method can also determine the percentage of each type of pathology but this requires a mathematical pattern recognition method. See the section on regression analysis below.

Finally, in contrast to histopathology, the MRS method has the advantage that it examines the entire piece of tissue that is placed between the transmit-receive coils thus removing any sampling errors associated with histopathological examination of only a fraction of the tissue sample.

Collection and Storage of Biopsy Specimens for Analysis

This is possibly the most important point of this chapter. If the biopsy specimens are not handled appropriately the tissue will start to degenerate and the important chemical species that have diagnostic and prognostic capabilities will alter.

For each tissue type reported to date handling protocols have been individually determined and reported [2]. Biopsy specimens can be a piece of tissue or a fine-needle aspirate biopsy (FNAB). The specimen must be immediately placed in a vial containing PBS/$D_2$0 after the biopsy is obtained and the vial placed without delay in a dewar containing liquid nitrogen. The polypropylene vials must have been tested for leakage of minute levels of chemicals which leach from the plastics and can cause cell death. This can be time consuming and often requires a number of batches of plastics to be tested. Similarly, the barrels of syringes used for FNAB need to be tested. Each tissue type, for example cervix, lung, kidney, has a finite time in which it can be stored in a freezer before the MRS examination is undertaken. It is unacceptable to store specimens for longer than 6 weeks.

The accuracy of the MRS method is dependent upon tissues and cellular pools of chemicals retaining integrity. In some of the earlier studies, tissue delivered to the pathology laboratory after surgery was then sent for MRS examination [10,11]. These spectra often displayed metabolite profiles characteristic of tissue degradation (e.g. increased lactate levels and depleted glucose). The predictive accuracy of such analyses was much lower than where the tissue was snap frozen immediately after collection.

Table 1: Resonances in one-dimensional ^{1}H MR spectra

Molecules	Abbreviation	Species	Chemical shift (ppm)
Amines			
Choline, phosphocholine, glycerophosphocholine	Chol	$-\mathrm{N}(\mathbf{CH}_3)_3$	3.2
Spermine, spermidine, polyamines	PA	$-\mathrm{NC}\mathbf{H}_2$	3.1
Creatine, phosphocreatine	Cr	$-\mathrm{NC}\mathbf{H}_3$	3.0
Lipids			
Triaclglycerol (fatty acyl chain)	Lip	$\mathbf{CH}_3-\mathrm{CH}_2-\mathrm{CH}_2-$	0.90
	Lip	$\mathrm{CH}_3-\mathbf{CH}_2-\mathrm{CH}_2-$	1.33
	Lip	$-\mathrm{OOC}-\mathrm{CH}_2-\mathbf{CH}_2$	1.6–1.7
	Lip	$\mathrm{CH}_3-\mathbf{CH}_2-\mathrm{CH}_2-$	2.02
	Lip	$\mathrm{CH}{=}\mathrm{CH}-\mathbf{CH}_2-$	2.08
	Lip	$-\mathrm{OOC}-\mathbf{CH}_2-\mathrm{CH}_2$	2.3
	Lip	$\mathbf{CH}{=}\mathrm{CH}-$	5.32
Amino Acids			
Alanine	Ala	$-\mathbf{CH}_3-\mathrm{CH}-$	1.49
Glutamate, glutamine	Glu, Gln	$-\mathrm{CH}-\mathbf{CH}_2-\mathrm{CH}_2-\mathrm{COO}-/\mathrm{NH}_{3+}$	2.2
Glutamate, glutamine	Glu, Gln	$-\mathrm{CH}-\mathbf{CH}_2-\mathrm{CH}_2-\mathrm{COO}-/\mathrm{NH}_{3+}$	2.6
Isoleucine	Ile	$-\mathbf{CH}_3$	0.97
Leucine	Leu	$-\mathbf{CH}_3$	0.97
Lysine	Lys	$\mathrm{H}_3\mathrm{N}^+-\mathrm{CH}_2-\mathbf{CH}_2-\mathrm{CH}_2$	1.7
Lysine	Lys	$\mathrm{H}_3\mathrm{N}^+-\mathrm{CH}_2-\mathbf{CH}_2-\mathrm{CH}_2$	3.03
Threonine	Thr	$\mathbf{CH}_3-\mathrm{CHOH}-$	1.33
Fucose	Fuc	$-\mathrm{CH}_2-\mathbf{CH}_3$	1.33
Threonine	Thr	$\mathbf{CH}_3-\mathrm{CHOH}-$	4.25
Valine	Val	$-\mathbf{CH}_3$	1.03
Other			
Lactate	Lac	$-\mathbf{CH}_3-\mathrm{CH}^-$	1.33
Citrate	Cit	$-\mathrm{OOC}-\mathbf{CH}_\mathrm{A}\mathbf{H}_\mathrm{B}-\mathrm{C(OH)}$	2.4–2.7
Taurine	Tau	$\mathrm{H}_3\mathrm{N}^+-\mathbf{CH}_2-\mathrm{CH}_2-\mathrm{SO}_3-$	3.25
Taurine	Tau	$\mathrm{H}_3\mathrm{N}^+-\mathbf{CH}_2-\mathrm{CH}_2-\mathrm{SO}_3-$	3.43

Care is needed to reduce or eliminate any minor and variable contamination of the sample. However, contamination with preparative agents (e.g. ultrasound gel, skin preparations) is inevitable during collection of biopsies of some tissue types. A robust pattern recognition method should be insensitive to such contamination.

Collection of a FNAB

A FNAB, which can be obtained from lymph nodes or any accessible lesion, usually comprises individual cells. It is important that for adequate signal-to-noise levels between one and five times 10^6 cells are obtained. To perform FNABs a 21/23 G needle is fitted to a 2, 5, or 10 ml syringe. After insertion of the needle tip into the tissue to be sampled the syringe plunger is withdrawn to about 1 ml to apply suction and the tip of the needle is pushed back and forth up to 20 times throughout the volume of the mass to be sampled without removal of the needle tip from the mass. The needle is withdrawn from the tissue, and the tip immersed in 300 μl PBS/D_2O in a prepared vial and the suction is then released. The buffer is aspirated into the tip of the syringe only and expelled back into the vial to wash out from the tip of the syringe and needle the cells aspirated from the tissue. No cells or liquid should be taken into the barrel of the syringe at any time. Gross contamination of the sample with blood should be noted as this may affect the quality of MR spectra. The vial is immediately placed in an upright position into liquid nitrogen and snap frozen.

Table 2: Summary of classifiers and spectral regions using SCS

Biopsy type (n)	Classification	Spectral regions (ppm)	Accuracy	References
Thyroid ($n = 107$)	Normal vs. malignant	Spectral identity not retained	99.0%	[22]
Brain ($n = 206$)	Control vs. malignant	23/55 Subregions	94.4%	[27]
Astrocytoma ($n = 91$)	High vs. low grade	0.81–0.85, 1.71–1.75, 2.16–2.20, 2.46–2.50, 2.54–2.58, 3.02–3.06, 3.51–3.55	95.7%	[28]
Breast FNA ($n = 140$)	Benign vs. malignant	1: 0.87–0.92, 1.20–1.25, 1.63–1.67, 1.79–1.82, 1.95–1.98, 2.85–2.87, 2.95–2.97, 3.19–3.33 2: 1.19–1.23, 1.32–1.38, 1.79–1.82, 1.96–2.00, 2.13–2.15, 2.70–2.76,2.92–2.94, 2.97–2.99	96.1%	[20]
	Lymph node involvement	1: 0.43–0.51, 0.64–0.77, 1.10–1.20, 1.56–1.59 2: 0.44–0.51, 0.67–0.71, 1.13–1.19, 1.56–1.60, 1.86—1.96	95.0%	[20]
Prostate ($n = 87$)	Benign vs. malignant	3.46–3.52, 3.40–3.46, 2.50–2.56, 2.14–2.20, 1.84–1.90, 1.12–1.18	96.6%	[21]
	Residual cancer after radiotherapy	0.77–0.82, 0.94–1.00, 1.32–1.37, 1.59–1.71, 2.24–2.27, 3.19–3.28	91.4%	[29]

Preparation of Specimens for MRS

Fine-needle Biopsy

Before ^{1}H MRS each fine-needle biopsy specimen is thawed at room temperature, then transferred to a 5 mm susceptibility-matched Shigemi MR tube. The volume is increased to 300 μl with fresh PBS/D_20 when necessary.

Tissue Specimens Can Be Handled in One of Two Ways

(A) The specimen is thawed and transferred together with the storage buffer directly to a 5 mm susceptibility-matched Shigemi MR tube.

(B) The sample is suspended in a constrained environment by means of insertion into a capillary tube [12]. This tube is then placed in a Shigemi 5 mm MR sample tube containing buffer and a reference standard. The goal here was to quantify the amount of each chemical with the weighed tissue.

It is important to note that freezing, storage, and thawing of tissue biopsies collected and stored in PBS/D_2O results in very significant and unpredictable leakage of metabolites into the storage buffer immediately upon thawing [13]. Leakage of metabolites is most exaggerated in small tissue samples such as needle core biopsies. For this reason the common practice of washing thawed tissue biopsies in D_2O is not recommended for biochemical characterization of tissue. Instead, biopsies should be collected, frozen, and thawed in a small volume (e.g. 400 μl) of buffer. With efficient water suppression techniques, such as Double Watergate [14], it is not necessary to attempt to replace any of the tissue water with D_2O prior to spectroscopy.

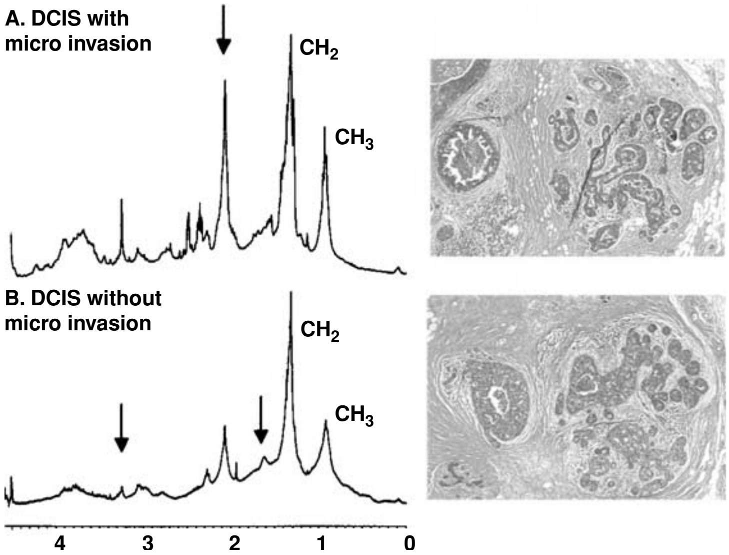

Fig. 2. ^{1}H MR spectra (8.5 T, 37° C) of fine-needle biopsy specimens obtained from breast ductal carcinoma *in situ*: (A) With microinvasion present and (B) without micro invasion. Tissue sections of DCIS are shown in (A) With microinvasion present and (B) without microinvasion. Spectra were acquired over a sweep width of 3597 Hz, 8192 data points, 256 accumulations, and relaxation delay of 2 s. *Source:* Reprinted from J. Women. Imaging. 2000;2:19–30. Lean CL, Russell P, Mountford CE. Magnetic Resonance Spectroscopy: A New Gold Standard for Medical Diagnosis. With permission from Lippincott Williams &Wilkins. (See also Plate 83 on page XIII in the Color Plate Section.)

All of the tissue and buffer should be within the sensitive region of the rf coils of the probe head so that diffusion of metabolites out of the tissue during the spectroscopy measurement does not result in loss of detected signal. This can be achieved by the use of Shigemi susceptibility-matched sample tubes. The maximum sample volume (tissue + buffer) that will fit within the sensitive region of the probe head will be specific to the particular probe head used. Care should be taken that all sample tubes are appropriately positioned in the probe head prior to measurement. The sample of tissue in buffer is spun at 20 Hz and shimmed optimally. In most cases a line width of 10 Hz for the residual water peak should be easily achievable. In a few cases, when examined with heterogeneous tissue samples, better shims can be obtained in the absence of sample spinning by adjustment of the *x* and *y* axis shims.

Experimental Temperature

There are several schools of thought on the appropriate temperature at which to run biopsy specimens. Much of the reported literature has MRS data collected at 37° C in an attempt to obtain data that can be correlated with *in vivo* spectroscopy. Clearly, at body temperature, the tissues degrade faster. Some groups have attempted studies at 4° C in order to reduce tissue degradation. However, it should be remembered that tissue and cell specimens contain a significant amount of lipid molecules. These lipid molecules undergo several phase transitions between 4 and 44° C [15]. It is imperative that the spectra that make up each database are collected at the same temperature.

Magnetic Field Strength

The majority of reported biopsy studies have been undertaken at the frequency of 360 MHz (8.5 T) [2]. There are some reports at 400 MHz (9.4 T) [16–18]. However, earlier work, predominantly on cultured cells, demonstrated that many of the diagnostic and prognostic spectra were frequency-dependent and thus care is needed.

MR Spectroscopy Methods

The most commonly performed measurement used for biopsy tissue characterization is a simple one-dimensional (1D) water suppressed ^{1}H spectrum. For a typical 50–100 mg (wet weight) tissue sample a spectrum of adequate signal-to-noise (SNR) ratio should be obtainable in 2–3 min. With manual sample changeover total preparation, spectrometer setup, and measurement time should be around 10 min per sample. Typical acquisition parameters for a 1D water suppressed ^{1}H MRS measurement are as follows.

Pulse angle 90° (6–7 μs), acquisition time 1 s, recycle delay 1 s, 8K data points, 128 transients, spectral width 3600 Hz, total acquisition time ca. 5 min. Water suppression can be effected by low power saturation during the recycle delay (presaturation) or, more effectively and selectively, by a selective excitation field gradient method (e.g. DPFGSE [14]).

As noted above, spectra acquired at different magnetic field strengths cannot be directly compared because, although proton resonance frequency is directly proportional to field strength, coupling constants are independent of field strength. Maximum SNR for a particular resonance of specific T_1 and T_2 is obtained under conditions of partial magnetic saturation with a specific flip angle and interpulse delay. In general, such conditions of maximum SNR will apply to, at best, a few resonances in the spectrum. It may be advantageous to choose flip angle and recycle delay to optimize SNR for specific resonances if these can be identified in advance of measurement. Flip angle, acquisition time, and recycle delay should be maintained constant for all measurements so that relative amounts of partial saturation are constant for samples with similar physical properties. For simplicity of data processing the spectral width and time domain should be maintained constant for all measurements. For samples of low cellularity the number of scans/acquisitions may be increased to obtain adequate SNR without detriment to the comparison of spectra from different samples.

After MR Spectroscopy

It is important to note that the correlation of tissue metabolite profiles by MR spectroscopy is critically dependent on rigorous histopathological assessment of the actual tissue examined by spectroscopy. To this end tissue should be transferred to fixative immediately after MR measurements are complete. The assumption that the histopathologic status of a tissue sample taken adjacent to the spectroscopy sample will be identical to that of tissue used for spectroscopy may be erroneous, especially in heterogeneous tissue types (e.g. prostate). As described earlier, routine preparation and examination of tissue for histopathological reporting may fail to detect the presence of prostate cancer in the spectroscopy sample [9]. Note that for the long-term goal of MRS-based tissue analysis to provide more rapid and sensitive diagnosis than routine histopathology it is necessary for the acquired spectra to be correlated with a more rigorous histopathological examination protocol than usual. Specifically, examination of 5×5 μm slices taken every 100 μm through the prostate tissue sample will ensure that all acini in the tissue sample are examined.

Assignments and Visual Inspection of the Data

The resonances of common chemical species found in the 1D ^{1}H MR spectra from human tissues are summarized in Table 1. These assignments have been made by different groups over 15 years. For review see [2]. Two-dimensional (2D) correlated spectroscopy has been used to make and confirm assignments [19]. See chapter on 2D methods in this Handbook. Many chemical species have been correlated with biological, diagnostic, and prognostic markers.

Typical spectra from malignant and benign breast cells obtained by aspirating the primary lesion are shown in Figure 3. The choline (3.25 ppm) to creatine (3.05 ppm) ratio clearly distinguishes the malignant and benign spectra (Figure 4). This ratio discriminates malignant and benign samples with an accuracy of 96% [20]. The four false positives, seen in Figure 4, are correctly classified when a more sophisticated pattern recognition analysis is performed [20].

The Complexity of Tumor Development and Progression

Another example of the complex and varying spectra that can occur during tumor development and progression is seen in Figure 5 where spectra from different types and pathologies of prostate tissue are seen. The simple resonance intensity ratio analysis described above for breast results in 80–90% accuracy for predicting malignancy [9]. For prostate the amount of data, spectroscopic, histological, and clinical, is considerable and difficult to analyze collectively by simple methods. Thus, a multivariate analysis method was developed [21,22] which formed the basis of the statistical classification strategy (SCS) described below.

Pattern Recognition Methods

A typical 1D MRS data set will have 4096 data points across the frequency spectrum. In contrast to simple resonance intensity ratio analysis described above where ratios of resonance intensities are compared, automated pattern recognition methods offer a more accurate and robust method with which to correlate MRS and clinicopathological characteristics. A method which combines a variety of pattern recognition procedures has been developed by Somorjai *et al.* [22] and is known as a "statistical classification strategy". The SCS method has been applied to a large number of systems and has been described in detail in a recent review [23] (see Table 1 for a summary).

The first stage of the SCS method uses an optimal region selector (ORS) to determine a small number of spectral regions that are most discriminatory [24]. To develop a robust classifier, the number of regions used to develop the classifier must be at least 5–10 times smaller than the number of spectra. The second stage uses these optimal regions and linear discriminant analysis (LDA)

to develop a classifier. Data are divided into training and test sets. The classifier is developed from the training set and then applied to the test set to see how well it does on data with which it has not trained. The original data are then mixed again and a different training and test set used to perform the same analysis. This is done up to 10,000 times to develop up to 10,000 different classifiers. This we call bootstrapping. The 10,000 classifiers are then used in combination to produce a final classifier. If at the end of stage 2 the accuracy of the final classifier is not sufficient, stage 3 of the SCS method is employed. Here other representations of the spectra, such as first or second derivatives, are used to make separate classifiers using stages 1 and 2. All stage 2 classifiers are then combined to yield a meta-classifier of increased accuracy [22].

In a study of FNAB from the breast, the data were subdivided into women with cancer with ($n = 29$) and without ($n = 32$) lymph node involvement [20]. Applying the SCS yielded classification of nodal involvement or not with sensitivity and specificity of 97 and 96%, respectively. Similar classification of patients with and without tumor vascular invasion yielded sensitivity and specificity of 84 and 100%. These classifications should be of great value in determining the therapeutic path for patients. More recent data from the same authors show great promise in calculating the tumor grade and estrogen and progesterone receptor status of breast tumors, also very important in planning therapy [25].

Regression Analysis

Routine histopathological reporting commonly includes a semi-quantitative description (e.g. "occasional foci," "extensive infiltration") of the amount of structural abnormality observed microscopically. Although imprecise, such semi-quantitative descriptions of observed disease burden are a factor in treatment planning. However, correlation of the MRS characteristics of tissue with histopathological characterization of the same tissue has largely been based on a simple two-class analysis in which tissue samples are classified according to the presence or absence of a single specific characteristic such as cancer. Diagnostic interpretation of the spectra from such mixed tissue voxels would ideally report not only the presence of disease, but also the extent or partial volume of disease within the volume of interest (VOI).

To address these two problems a linear regression analysis was undertaken on spectra acquired from 82 cancer-containing prostate tissue specimens. MR spectra were correlated with serial section histopathological examination of each tissue specimen for which the volume fraction of cancer tissue was estimated in 5% increments. A classifier based on five spectral features developed from a training set of 45 randomly chosen spectra was used to predict from spectra the volume fraction of cancer in a validation set of 37 tissue samples. The overall accuracy of predicted cancer volume, measured as the average accuracy of all cancer volume estimates, was 96% [26].

Future Challenges

Putting magnets into a pathology environment is a new concept. The challenge is to move this technology into a routine clinical environment. This was achieved by Liposciences for serum lipoprotein analysis of serum (www.liposcience.com). Serum specimens are easier to transport and the test is for screening purposes.

Clinical acceptance testing is required and is currently being undertaken in Sydney by a group of endocrine and urology surgeons. They need to verify that the tests provide additional information that is necessary for the management of the patient.

Automation of the software to drive the system and to allow comparison of spectra with classifiers will see the spectroscopy method for analyzing human pathology move into a new age.

Acknowledgments

We thank Deborah Edward, Brooke O'Donnell, Sinead Doran, and Raquel Baert for assistance in preparing this manuscript. Our thanks go to all present and past collaborators in particular Professor Peter Russell and Dr. Ray Somorjai, without whom none of this would have been possible.

Functional MRI

Graeme D. Jackson, Regula S. Briellmann, Anthony B. Waites, Gaby S. Pell, and David F. Abbott
Brain Research Institute, Melbourne, Victoria, 3081, Australia

Principles of fMRI

In recent years, it has been demonstrated that MRI is capable of detecting changes in cerebral blood volume, flow, and oxygenation that accompany a change in neuronal activity. MRI techniques that observe these activation-induced signal changes are termed "functional MRI" (fMRI).

The most common contrast mechanism in fMRI is known as blood oxygenation level dependent (BOLD) contrast, first described by Ogawa *et al*. This contrast mechanism relies on the relationship between local changes in oxygenation and blood flow that occur with neuronal activation. The sequence of events is as follows:

1. The neuronal cells fire.
2. The small amount of energy used is recovered via oxygen metabolism, resulting in a small increase in deoxyhemoglobin in the first second or two after cell firing.
3. A vascular response also occurs, being a local increase in blood flow (perfusion).
4. In the next few seconds, the delivery of oxygen via the vascular response is far in excess of that depleted to meet the local energy demands. Therefore, paradoxically, there is a local *decrease* in the concentration of deoxyhemoglobin of a much greater magnitude than the initial increase.

BOLD contrast relies on the sensitivity of MRI to detect the changing concentration of deoxyhemoglobin. The initial small increase in deoxyhemoglobin has been observed by some groups as a very small "initial dip" in the time course of the BOLD MR signal; however, it is the subsequent larger decrease in deoxyhemoglobin concentration that provides the substantial and robust signal increase that makes the method most useful. The signal change arises because deoxygenated hemoglobin is paramagnetic, whereas oxygenated hemoglobin is diamagnetic. Paramagnetic molecules are especially visible in MRI since they exert a strong enhancing effect on the relaxation rate of the water in the vascular environment. The transverse relaxation times, T_2 and T_2^* are reduced by this mechanism. These are the contrast dependencies of spin echo and gradient echo images, respectively. Both these basic imaging techniques can therefore be used to detect BOLD contrast. Differences between these two techniques exist with regard to the extent of sensitivity to the environmental change. The T_2^* relaxation time is uniquely sensitive to the intravascular changes of water environment and therefore BOLD contrast is magnified in gradient echo images. Currently, the most commonly applied imaging technique for BOLD fMRI is echo planar imaging (EPI). It allows very rapid imaging, allowing for whole brain coverage with standard paradigms.

Another more recently developed contrast mechanism for fMRI is that of perfusion. This utilizes imaging methods that are sensitive to detecting the local change in blood flow which is the initial response to the neuronal firing. This technique acts as a more direct means of detecting the activation site. However, the perfusion imaging methods suffer from limitations in signal-to-noise ratio (SNR) in comparison with the simpler BOLD imaging techniques.

Design of fMRI Trials

One of the most important parts of an fMRI experiment is the designing of the appropriate paradigm that will allow identification of brain voxels involved in a particular cognitive or sensory–motor function. In this chapter, we will discuss two commonly used approaches, the "block design" and the "event-related design." For both approaches, it is important to keep in mind that the vascular response (which is what we can measure with BOLD) follows the neuronal activity (which is what we would like to know) with a delay of several seconds.

Block Design

The simplest form of a design for fMRI experiments is called a block design. This comprises alternating cycles of periods of task and rest conditions (Figure 1). Each task and rest period should not be too short, as the BOLD signal takes around 5–10 s to reach a maximum after a neuronal event. Shorter periods will lead to a reduced contrast between task and rest states. Very long periods also have a drawback, as they may resemble the low frequency fluctuations or drift in the scanner signal. Such a design would lead to confusion between the cognitive variation, which we wish to measure, and artifactual changes, which we

Graham A. Webb (ed.), Modern Magnetic Resonance, 1037–1050.

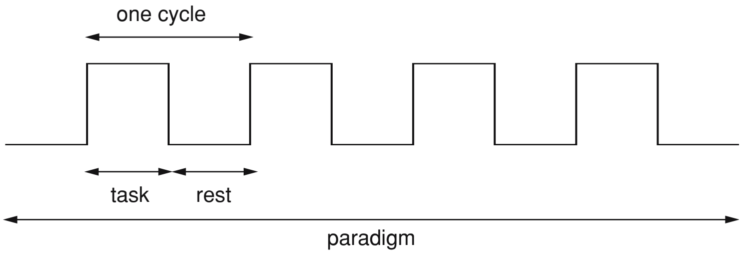

Fig. 1. Scheme of a block design paradigm with alternating block and task periods of identical length.

wish to minimize. The ideal design allows the BOLD signal to reach a steady state within each condition in order to maximize contrast. In practice, a 40 s to 1 min cycle time (i.e. 20–30 s task then 20–30 s rest) with about 5–8 cycles, giving a total experiment time of 4–10 min is suitable for many experiments. With more robust tasks (such as visual stimulation, which leads to large neuronal response) and higher magnetic field strengths, such as 3 T, the total experiment time may be reduced. Longer experiment times increase the chance of motion artifacts due to subject discomfort, as well as loss of concentration on the task.

Block design experiments allow maximization of SNR, but also have some disadvantages. Repeating the same task may lead to the subject anticipating the task and sometimes even the response. This may considerably confound the results. A randomized design avoids this issue since the occurrence of a particular task type is unpredictable. Further, not all cognitive studies can be adapted to a block design. For example, experiments assessing the cognitive effect of an unexpected stimulus within another task, known as an oddball paradigm, cannot be performed in a block. Similarly, studies assessing unpredictably occurring physiological events, such as myoclonic jerks, cannot be performed as block designs. Block designs also do not provide information on the shape of the blood flow change in response to the task. This vascular response to a neuronal event is referred to as the hemodynamic response function (HDR). The HDR is used in event-related designs.

Event-Related Designs

Event-related designs are a more flexible approach, and involve the placement of single events within a train of “rest state” conditions. The order of the events is often randomized, preventing anticipation of the task. Events with varying periods of rest allow measurement of different parts of the hemodynamic response, allowing the HDR to be identified. This can be useful in understanding the different response from different brain regions, which may be a result of either the different vasculature of the region, or the differences in cognitive dynamics in the different regions.

The disadvantage of such designs is the low SNR. This is due to the fact that the task state is not sustained for long periods, leading to a less intense vascular response. This can be partially overcome by using “clustered” random presentation of events, where the random pattern of task events is chosen so that there are clumps of task and clumps of rest, albeit with some variability. This is a compromise, giving some increase in SNR whilst maintaining the benefits of a random design.

Event-related analysis techniques can also be applied to data from a block-designed study. This can either take the form of modeling the block of task as a series of events, or performing a *post hoc* analysis of the data. The *post hoc* analysis involves identifying events within a block, such as correct responses to a stimulus, and comparing them to for example incorrect responses.

Inter-Stimulus Interval Selection for Event-Related Designs

It is important to consider the inter-stimulus interval (ISI) carefully. One must first decide whether a sparse or rapid event-related design is to be used. Sparse designs have a long ISI such that the hemodynamic response returns to baseline before the next event is encountered. More common are rapid event-related designs where the minimum ISI is often as little as 2 s. These designs have the advantage that they are more efficient (many more events are captured in a given period of time), and they are therefore the preferred choice if the nature of the task allows it. One must be more careful with these designs, however, as analysis methods usually rely on the assumption that the BOLD response to multiple events adds linearly. This is not always the case (especially if the ISI is much less than 2 s), and one must be careful when interpreting results in brain areas where the linearity of the BOLD response is not well known.

Other issues should also be considered when choosing the ISI. The use of an ISI equal to an integer multiple of the repetition time (TR) can lead to a missed peak in the HDR. This occurs because the stimulus and measurement are synchronized, and measurements may repeatedly occur before or after the peak of the HDR. Making matters worse, there would be a systematic difference in the time each individual slice in a single volume is acquired relative to the event, so that some slices may always be more sensitive to the event than others. If synchronous timing is to be used, it is therefore best to choose an ISI that differs from the TR such that measurements of the HDR occur at different times for many successive events. For example, if events were timed to occur each 1.3 × TR, the HDR would be effectively sampled at nine different time points before the sampling pattern began to repeat. This would be better than 1.5 × TR, for example, where only two different time points would ever be sampled. Another approach is to use jittering. Jittering involves randomly varying the ISI slightly for each event, which again leads to measurements at different points throughout the HDR.

Modeling the Hemodynamic Response in an Even-Related Study

Analysis of an event-related study requires a specific model for the HDR. If the primary goal of the experiment is to determine the precise form of the HDR, a flexible basis set is usually chosen such as a set of sine and cosine waves (a Fourier set), or a set of Gamma functions. On the other hand, if the goal is to determine where and when an event occurred, a canonical HDR is typically used. The canonical HDR is an empirically determined shape found to fit experimental data. One can improve the canonical model by including the temporal derivative (which allows flexibility in the delay of the HDR) and a dispersion term to allow a broader than typical response. This can accommodate some regional and inter-subject variation in response. The canonical model is the most powerful at detection, since it has the fewest parameters, and thus preserves the highest number of degrees of freedom. Conversely, the basis function approaches will be more sensitive if the response differs significantly from the canonical form. A combination of approaches is possible. For example, a portion of a study can be dedicated to eliciting the regional shape of the HDR in an individual (perhaps with a stimulus known to yield a large signal change), and this can then be used as a more accurate model for detection of subtle stimuli in that individual.

Principles of Experimental Design

Where to Start?

There are many factors that affect detection power including the type of experimental design, the scanner, the population, and the nature of the task being imaged. In order to identify the optimal task, a clear hypothesis will aid greatly in designing the experiment. Such a hypothesis may be based on theoretical background of a particular function, or more commonly, is an extension of an observation made outside the scanner. The development of an appropriate task for fMRI scanning is often based on published, somewhat similar paradigms. A protocol can then be further refined after a few pilot studies have been undertaken. Typically, the durations of the final protocol should be a little longer than the estimated optimum, as the subjects used for pilot studies are often highly motivated individuals who will give better results than the average study population.

Block or Event-Related Design?

The block design is optimal for determining the location of activity, but cannot readily be used to determine the nature of the HDR time course. Event-related designs could be optimized to efficiently determine the nature of the HDR time course; however they generally offer much less power to prove that a response actually exists at a particular location. There are many subtleties to possible designs, including hybrid block and event-related designs. In general a block design is preferred if there are no contraindications, as it gives higher statistical power. Alternative approaches should be taken only for questions that cannot be answered using a block design.

Baseline Considerations

Choosing the appropriate baseline is as important as choosing the optimal task. Commonly, the baseline consists of "rest," during which the subject is asked to do "nothing." This is a very poorly defined state, and some paradigms improve with a more defined, engaging baseline. Contrast in fMRI arises from a measured *change* in signal, and it is therefore important to know from what baseline state the signal changed. Our brains are always "on," so one must be careful when interpreting signal change related to a task. All we can really say about significant activation is that there is greater signal whilst a subject is performing a task of interest than when they are performing the baseline task. Rest can and should be considered as just a different task than the task of interest. Similarly, if signal decreases during the task of interest, one can regard this as an increase in activity during rest. Importantly, signal decrease or "deactivation" is not the same as inhibition, since inhibition is itself an active process that can contribute to an increase in signal. If inhibitory processes are involved, the reduction of activity that is observed may have been signaled from an active inhibitory process adjacent to or some distance from the site of "deactivation."

Performance Measures

Proper interpretation of fMRI results generally relies on knowledge of the tasks subjects were performing during the imaging session. One common assumption is that the subjects are doing what they are told. Ideally performance measures should be undertaken concurrently with the imaging, but this is not always practical. For example, in a commonly used language paradigm subjects may be asked to generate as many words as they can that begin with a provided letter. To avoid problems associated with subject motion, this task is normally performed covertly (i.e. without vocalization). This task performance cannot be directly verified. To minimize the possibility of incorrect interpretation, one should obtain some measure of task performance. This is often the measurement of a subject's performance on a similar task out of the scanner. Subjects should also be asked after their scan whether or not they encountered any difficulty in performing the task in the scanner.

Improved interpretation of functional imaging results can often be made when performance of aspects other than the task of interest are also measured. For example, it is known that changes in physiological measures such as cardiac and respiratory rates can affect the cerebral circulation, and breath-holding especially can result in very large changes in the BOLD response that can potentially confound interpretation. Measures of skin conductance and eye tracking are also possible, and these and other measures can be used to remove variance in the data that may be unrelated to the task of interest, or to explicitly model effects that may be related to the task of interest.

Principles of Analysis

There are a number of steps involved in taking raw fMRI data and turning it into colored maps of activity that can be readily interpreted. The processing pipeline contains procedures to minimize artifact, maximize signal, and aid interpretation. We will describe here a commonly used imaging pipeline for BOLD fMRI.

Data Preparation

Often the first step in an analysis pipeline is extraction of the imaging data from the scanner and conversion into a format suitable for further processing. Whilst scanner manufacturers are slowly introducing functional image analysis tools into their standard software, at the present time such software is often rudimentary and inflexible.

Pre-Processing

Pre-processing steps are those performed prior to statistical image analysis. Depending upon the type of acquisition they can include:

- *Correction for signal drop out near magnetic susceptibility inhomogeneities.* The variation in magnetic susceptibility especially near tissue–air boundaries can cause extensive areas of signal loss in typical EPI acquisitions due to the inability of scanners to shim to a uniform field in these regions. Various methods have been devised to overcome this problem, including the z-shim method that involves acquiring two or more sequential acquisitions with different imposed corrective gradients that effectively image separately the areas of drop out. A post-processing step is required to combine these multiple acquisitions.
- *Correction for geometric distortion*, e.g. Measured B_0 phase maps can be used to calculate and correct for geometric distortions that plague EPI fMRI images.
- *Slice timing correction.* Acquisition volumes most commonly consist of a series of sequentially acquired slices. Slice timing correction methods generally resample the temporal response of a voxel, applying interpolation to estimate what the response would be at the time of commencement of each acquisition volume. Of course this correction should not be used in conjunction with imaging methods that involve acquisition of an entire volume in one imaging shot.
- *Gross motion rejection and/or realignment.* The deleterious effects of subject motion can be reduced with these steps. Gross motion rejection can also remove data contaminated by acquisition failures such as a gradient misfire.
- *Global intensity normalization*. This step is necessary with some scanners that are not able to provide a stable signal from one acquisition to the next. If one assumes that the BOLD signal change due to the task is small relative to the mean signal of all within-brain voxels, one can normalize the global signal to a common value (proportional scaling). Unfortunately, the BOLD signal change is not always negligible in relation to the mean global signal, so there is a risk that this processing step will do more harm than good (for example by reducing the apparent size of real activation). If the MRI system is reasonably stable, then global intensity normalization should usually be avoided.
- *Spatial normalization.* This step involves registration of the imaging data of each subject in a study to a common template, to enable voxel-wise statistical analysis of group data and/or to allow reporting of activation locations relative to a standard atlas. In the case of a single subject analysis, the derived transformation may

be applied to the statistical result instead of the raw imaging data, so as to avoid resampling artifact. If this is done, nearest-neighbor resampling is used to preserve the fidelity of the statistical result.

- *Smoothing.* Spatial and temporal smoothing with a Gaussian kernel is often performed to improve the SNR of imaging data. This pre-processing step also ensures that the variance distribution is Gaussian, allowing the valid application of Gaussian random field theory in statistical analysis. To achieve this, the smoothing kernel should have a full width at half maximum (FWHM) of at least twice the voxel size.
- *Linear de-trending.* This is a controversial processing step as the underlying assumption that a linear trend in a voxel time course is "noise" is unlikely to be valid. There are other ways to deal with this later when statistically analyzing the images.

It is important to note that the order in which these processing steps are performed can have a substantial effect on results. The order listed above is a typical scenario, however, it may not always be the best arrangement.

Statistical Analysis

Statistical analysis of fMRI data is necessary because the signals of interest are usually of a similar magnitude to the noise in the data. By collecting many images and applying statistical analysis, one can enumerate the voxels that have an acceptable probability of being associated with the task of interest. The most common method of analysis is a general linear model based approach. The signal is assumed to comprise a linear combination of effects of interest, confounding effects, and a random noise term. The effect of interest in the model usually consists of a function representing the time course of tasks performed convolved with an estimate of the brain's HDR. Confounding effects are also often included in the model, such as the realignment parameters determined in the motion correction pre-processing stage (these are often included to model any residual motion effects such as changes in the magnetization experienced by protons that are not corrected by realignment). The statistical analysis determines, for each voxel independently, the proportion of included model terms that best fit the measured data, and provides an estimate of the probability that the coefficient of the effect of interest is non-zero (implying the effect is present). Gaussian random field theory is often used to estimate a probability corrected for the multiple comparisons made in this massively univariate data.

Other statistical analyses are also possible, including data driven approaches where no assumptions are made about the tasks performed. Rather the data are interrogated in such a way as to extract structured components that are able to describe the data in some way. Such methods include principle components analysis and independent components analysis, the latter generally being more useful in the neuroimaging context. Detailed descriptions of these approaches are beyond the scope of the current discussion. However, it is worth noting that these approaches are beneficial when the nature of the expected response is not known. Results of data driven analyses can be difficult to interpret however, and model based approaches are generally more powerful when a good estimate of the expected response is available.

Software Packages

There are now a number of software packages available to assist with functional imaging analysis. Probably the package in most widespread use is SPM, a powerful and flexible package for performing "statistical parametric mapping." A comprehensive competitor with some unique advantages is FSL. Both of these packages are available free of charge. There are many other packages that are also worth considering, including several specialized utilities that have been designed to perform particular aspects of processing, analysis, and/or visualization. Often the best analysis approach will take advantage of several packages. Selection can often be a matter of determining the packages that are already in use in your geographical area, since an experienced user is often the best source of help for inexperienced users.

Artifacts and Pitfalls

Since fMRI studies usually require a relatively long series of scans in order for the activation-induced signal changes to build up to a detectable level, gross subject motion may occur. Image processing techniques exist to at least partially correct for motion, as we discussed earlier, however prevention is better than cure. For example, head immobilization via straps, vacuum-bean bags, and/or use of bitebars can help minimize head motion. Immobilizing the upper part of the extremities during sensory–motor tasks can help minimize task-related motion. A further confounding factor can be task-associated physiological effects resulting in changes in brain activation, such as subconscious breath-holding during challenging tasks. Such artifacts may lead to misinterpretation of the study results, and every effort should be undertaken to minimize their occurrence and to monitor for their presence.

Another common problem with fMRI is geometric distortion. The most common rapid imaging technique for fMRI is EPI. With this technique, images of the brain can be acquired in times of 100 ms or less; however the technique is particularly prone to exhibit geometric distortion.

This is especially severe in areas of high susceptibility differences such as the air–tissue boundary in the temporal lobes. Correct interpretation and detection of fMRI changes in these areas is often difficult. Even in relatively susceptibility-free regions of the brain, EPI images will display subtly different distortions in comparison with slower structural scans and this complicates the overlay of function and structure that is a necessary for interpretation of results.

Even when all these problems are minimized, and an appropriate activation map has been generated, one has to be careful in the interpretation of the fMRI results. A common pitfall in group studies is an inadequate number of participants, leading to group results that do not survive correction for multiple comparisons. Whereas such results may be important pilot data, directing further experiments, one has to consider that they are at best a "trend" and provide no statistical proof of an effect greater than noise. A further common problem is the interpretation that a significant "activation" is equivalent to preserved function. There are many examples in the literature, demonstrating that the degree of activation does not linearly follow performance of a function. A very poor performer and an excellent performer may both activate relatively few areas, whereas a moderate performer may show a relatively higher degree of activation. Task-related activation in a particular area may not represent "the site" of a particular function, but rather represent part of a network of areas used to perform this task, or even an associated function, such as attention to the task or eye movements in relation to the paradigm. Furthermore, just because an area is active does not necessarily mean that it is essential for the performance of the task.

Practical Applications

All the fMRI examples shown here were acquired on a GE Signa 3 Tesla MR scanner (GE Medical Systems). Higher magnetic field strength is associated with a higher SNR, which can be translated into shorter imaging times for a given resolution, or higher resolution for a given imaging time, or combination of both. At the time of writing 1.5 T scanners are most common. Compared to 1.5 T, at 3 T the same fMRI paradigm could be run for a shorter period of time, or paradigms evoking typically a very small response may give sufficient signal, whereas they may not be useful at lower field strength. However, the higher field strength has also some disadvantages. There is the potential for greater energy deposition into tissue and increased susceptibility-related artifacts.

Functional images are always acquired together with other sequences. The T_2^*-weighted sequence used for fMRI has a low resolution, so T_1 or T_2-weighted images are usually acquired in the same planes as the T_2^*-weighted images. Further, angiogram/venogram images are often acquired to localize vessels in the brain, in order to avoid confusion of a signal arising from a vessel with the BOLD response. fMRI in the examples below was performed using a whole brain (22 slices) gradient EPI technique (TE = 40 ms, TR = 3600 ms, acquisition matrix = 128 × 128, flip angle = 60°, and 4 mm thick slices, 1 mm gap).

Language fMRI

Language is a cognitive brain function that involves a network of brain areas. In the majority of healthy subjects, these language-related brain areas are predominantly in the left hemisphere. Since the first reported use of fMRI for the study of language in 1993 by McCarthy *et al.*, fMRI has become established for the purpose of assessing language lateralization. The determination of "language dominance" is an important investigation step in patients undergoing brain surgery. Many different language fMRI tasks have been developed. Some are designed to activate particular parts of the language network. In our Institute, we have developed and validated two language paradigms, both performed as a block designs.

For the orthographic lexical retrieval (OLR) paradigm a letter is presented visually, and the subject asked to retrieve silently as many words as possible beginning with that letter. After 18 s a second letter is presented, giving a 36-s task period. For the noun–verb generation (NVG) paradigm, the subject is visually presented with a common noun (e.g. fish) and is asked to generate an appropriate verb (e.g. swim). A new noun is presented every 4 s, with a task period of 36 s. For both tasks the baseline consists of visual fixation of a cross hair, this rest period also has a duration of 36 s (Figure 1). Both paradigms have four cycles with an additional rest period at the start of the paradigm; the total duration of the paradigm is 5.4 min.

Determination of Language Lateralization

Image processing, as described above, will result in maps of activation; these can be used to quantify the lateralization of a function. The laterality index (LI) is based on the number of activated pixels in language-associated areas. The LI is calculated using the following equation: LI = (left-hemispheric pixel count—right-hemispheric pixel count)/(left-hemispheric pixel count + right-hemispheric pixel count).

Examples of fMRI Language in Controls

We recently performed a study in multilingual subjects using a NVG task in four different languages. For reference to this publication, see figure legend. We hypothesized that the degree of proficiency in each language would be related to the extent of functional activity measured in a region of interest analysis. Therefore, the degree of

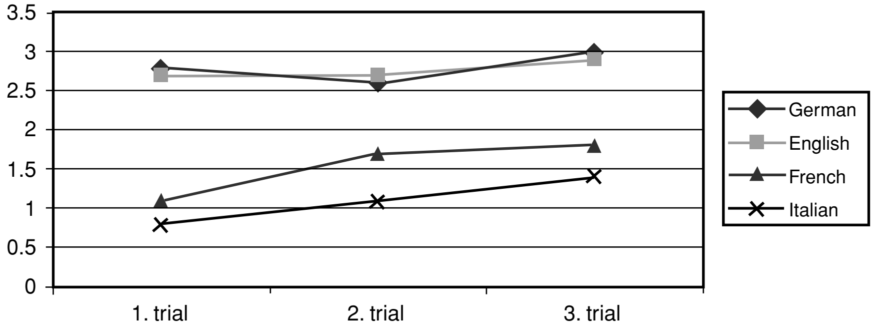

Fig. 2. This diagram shows an example of an out-of-scanner performance test in a quadrilingual subject. The subject was given a cartoon with a word-free story, and was asked to produce a discourse based on this cartoon. This was repeated three times, and then a new cartoon was given to assess the discourse in another language. Results are given for the words/second produced at all three trials. Note the overall increase in word production, particularly noticeable for languages with poorer proficiency. This subject had two "good" and two "poor" languages. *Source:* Adapted from Briellmann RS, Saling MM, Connell AB, Waites AB, Abbott DF, Jackson GD. A high-field functional MRI study of quadri-lingual subjects. Brain Lang. 2004;89:531–42.

proficiency in each language had to be quantified in detail. We used several tests, including a discourse test, in which the subjects were asked to produce a story based on a cartoon, which displayed a word-free story. Figure 2 shows the results in one subject, demonstrating a clear difference between languages with good performance (in this subject German and English), and languages with poor performance (Italian and French). The fMRI showed that all four languages activated overlapping brain areas, corresponding to the major language regions (Figure 3). Interestingly, the number of activated voxels correlated with proficiency, so that the activated volume increased for languages in which a subject had poorer proficiency. This observation highlights an important issue in the design and interpretation of fMRI experiments. In some cases better performance is associated with more brain activity, whilst in others the reverse is true. Correct interpretation of a novel task therefore requires some independent measure of subject performance or response.

Examples of fMRI Language in Patients

Atypical language lateralization is more frequently found in patients with epilepsy and some other focal and chronic brain disorders. In a series of 30 healthy controls and 30 epilepsy patients, we confirmed the increased frequency of atypical language in epilepsy patients (Figure 4). Such atypical lateralization may represent reorganization due to early disturbances of the left hemisphere, such as a perinatal vascular event. fMRI is not only used to determine language lateralization, it has been used to assess the

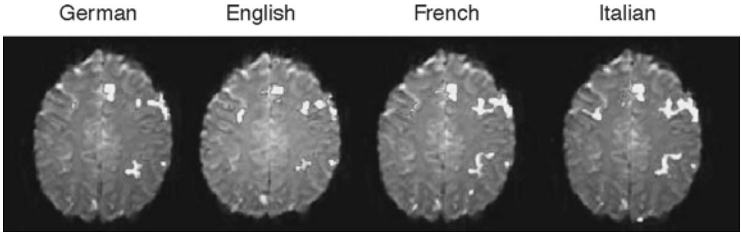

Fig. 3. Functional MRI of language of a quadrilingual subject. The subject performed the NVG task in four different languages. The figure shows the activation during task in comparison to rest in all four languages. Note that all languages activate similar brain areas, however, there is a subtle increase in the amount of activation in poor compared to good languages. *Source:* Image taken from Briellmann RS, Saling MM, Connell AB, Waites AB, Abbott DF, Jackson GD. A high-field functional MRI study of quadri-lingual subjects. Brain Lang. 2004;89:531–42. (See also Plate 84 on page XIII in the Color Plate Section.)

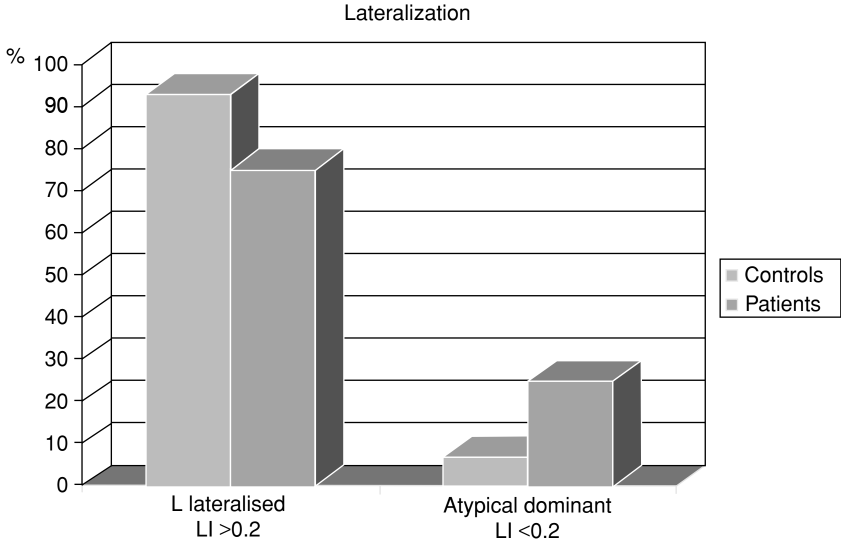

Fig. 4. This diagram shows the distribution of typical and atypical language lateralization in a group of 30 healthy controls and 30 patients with refractory partial epilepsy. Note the predominance of left-lateralized language in both groups, but the relatively higher proportion of atypical language in the patient population.

spatial relationship between the seizure focus and brain function (for review see Sunaert and Yousry 2001). This is of particular interest in the planning of neurosurgical resection.

Figures 5 and 6 show findings of a 9-year-old girl who was investigated for possible epilepsy surgery. Her epilepsy was first noted at the age of 5 years, when she developed complex partial seizures, occurring in clusters, often out of sleep. Her structural MR investigation showed a left mesial temporal lesion, suggestive of a low-grade tumor (Figure 5). Her language fMRI shows clear left-lateralized language dominance (Figure 6). Therefore, in this case language and seizure focus were co-lateralized to the same hemisphere.

A different situation is present in the patient described in Figures 7 and 8. These figures show the findings of a 35-year-old woman, who is left-handed. Her epilepsy started at the age of 12 years. Her EEG showed two independent, left-hemispheric epileptogenic foci, one in the occipital region, the other in the mesial temporal lobe. Her structural MR shows a left occipital lesion, suggestive of an old hemorrhagic lesion (Figure 7).

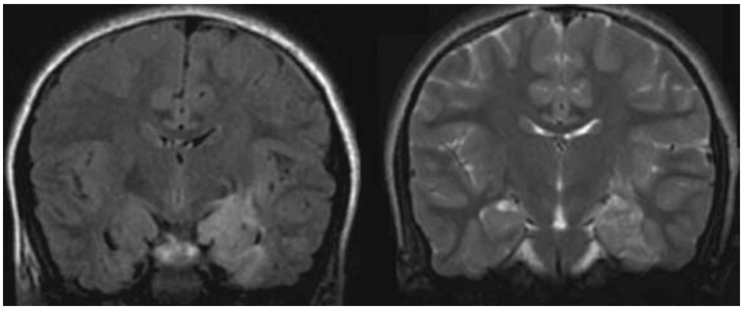

Fig. 5. This figure shows the structural MR examination in a 9-year-old girl with temporal lobe epilepsy. Representative coronal slices in the area of the mesial temporal lesion are shown. On both the FLAIR (left) and T_2-weighted (right) scans, the lesion is characterized by heterogeneously increased signal intensity, affecting mainly the mesial temporal area, but also partially involving the stem of the temporal lobe. This pattern is indicative for a low-grade tumor, such as dysembryoplastic neuroepithelial tumor.

Analysis performed using software developed by David Abbott,
Brain Research Institute, Melbourne, Australia

Fig. 6. Language fMRI in the same patient as shown in Figure 5. There is strong left-lateralized language dominance, with particularly strong activation in the frontal lobe language areas (middle frontal gyrus and inferior frontal gyrus). There is also activation in the superior temporal gyrus, which is not involved in the lesion. Therefore, language and seizure focuses were co-localized to the same hemisphere. Note: the subject's left is displayed on the image right (i.e. radiological convention). (See also Plate 85 on page XIV in the Color Plate Section.)

Based on the clinical symptomatology, this lesion was considered the primary seizure focus. Additionally, there were also signs of ipsilateral hippocampal sclerosis, suggestive for secondary damage. Her fMRI of language shows right-lateralized language dominance (Figure 8). Therefore, in this case language and seizure focus were in different hemispheres, and given the suspected early left-hemispheric damage, shift of the language function to the undamaged right hemisphere may have taken place.

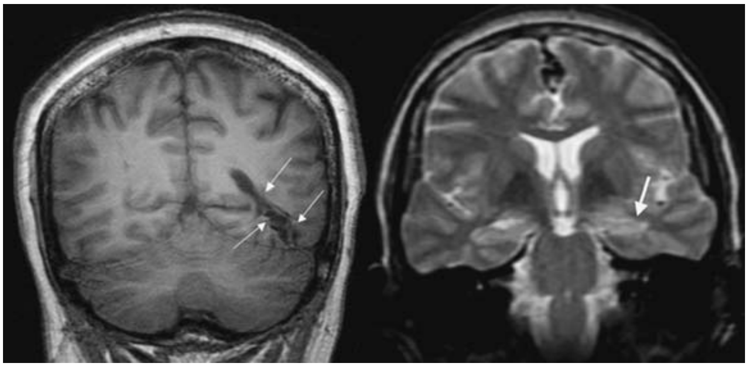

Fig. 7. Structural MRI of a 35-year-old women with refractory partial epilepsy. The image on the left shows a T_1-weighted, coronal slice at the level of the left occipital abnormality (highlighted by thin arrows). The image on the right shows a T_2-weighted, coronal slice at the level of the hippocampus (highlighted by thick arrow). There is increased T_2-weighted signal in the body of the hippocampus (114% of mean normal value, whereas the empirically determined cutoff indicating an abnormally increased value is 105% of mean normal value).

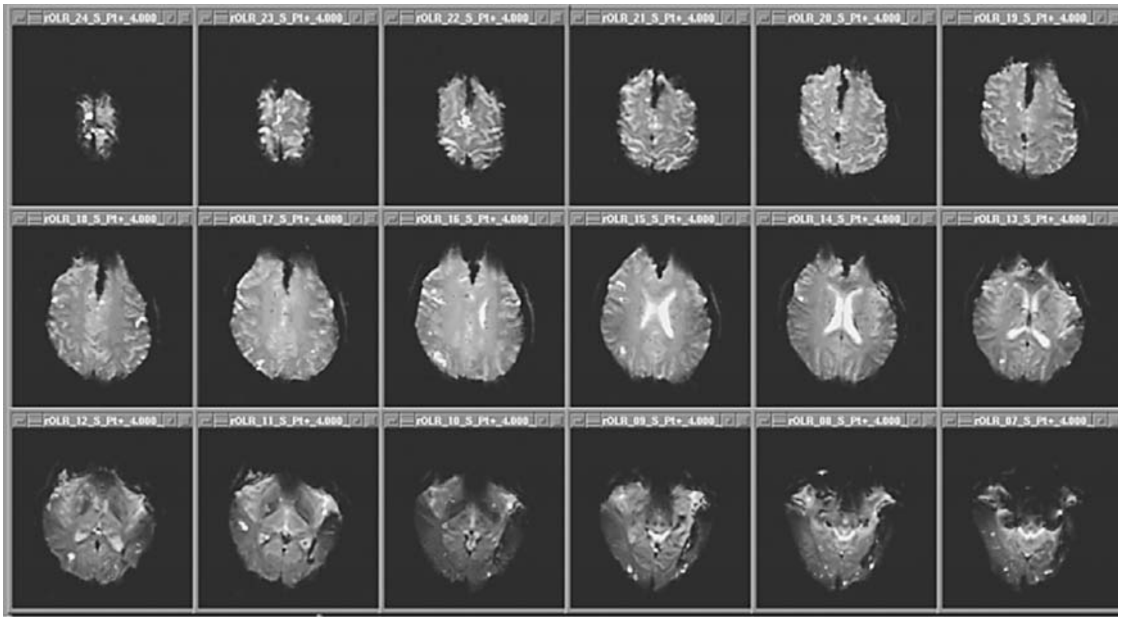

Fig. 8. Language fMRI in the same patient as shown in Figure 7. There is strong right-lateralized language dominance, involving both frontal and temporal lobe areas. In this left-handed patient, language and seizure focus were not co-localized (see text for more details). Note: the subject's left is displayed on the image right (i.e. radiological convention). (See also Plate 86 on page XIV in the Color Plate Section.)

FMRI/EEG

Some neurological diseases are associated with changes on the electroencephalogram. Probably the best-known example is the epileptiform discharge in patients with epilepsy. These discharges can occur without associated clinical symptomatology, and are termed interictal discharges. These discharges can be used as "events-of-interest" in an fMRI paradigm. This technique has a great practical potential for the investigation of patients with focal epilepsy. Interictal focal discharges typically originate from around the seizure focus, and can therefore be used as a localization indicator. However, whereas the EEG gives excellent temporal information on when these discharges occur, it has rather poor spatial resolution. The combination of EEG and fMRI overcomes this limitation. Until relatively recently, recording of EEG within the bore of the magnet has been regarded as too difficult since the EEG signal is impaired due to factors including induced currents from slight movement of leads in a large static magnetic field, changing magnetic field gradients during the scanning procedure and the radio frequency (RF) energy emitted by the transmitter coil. The MR image itself can be further impaired by RF interference from conductors and electrical devices within the magnet. However, these problems have been gradually overcome, and an increasing number of centers are reporting successful EEG recording within the scanner. This approach allows studying fMRI activation in association with subclinical events.

The quality of the EEG during scanning is of crucial importance for the fMRI/EEG analysis. Our system is now of a quality that allows discrimination of the interictal discharges during continuous fMRI scanning. Figure 9A demonstrates the high quality of the EEG obtained during scanning and Figure 9B shows further improvement of the EEG using post-processing methods (Figure 9). In suitable patients, fMRI/EEG can show focal activation in the area of the presumed seizure focus, as demonstrated in Figure 10.

Conclusion

fMRI is a relatively young investigation method. Nevertheless, it has proven to be a very useful diagnostic and research tool. fMRI is safe, non-invasive and can be repeated as many times as needed. Due to the need for active participation of the subject it can, however, only be applied to cooperative subjects. Typically, this is difficult to achieve

Fig. 9. Example of EEG recording during scanning, at the time of an epileptiform discharge. (A) The image shows the EEG before post-processing, demonstrating the quality of our EEG during scanning. A run of rhythmic theta is seen with maximum over C4. (B) The image shows the same trace after filtering. Note the disappearance of residual gradient artifact after filtering, allowing one to appreciate the sharp transients associated with the theta waves. For the analysis of this study, see Figure 10.

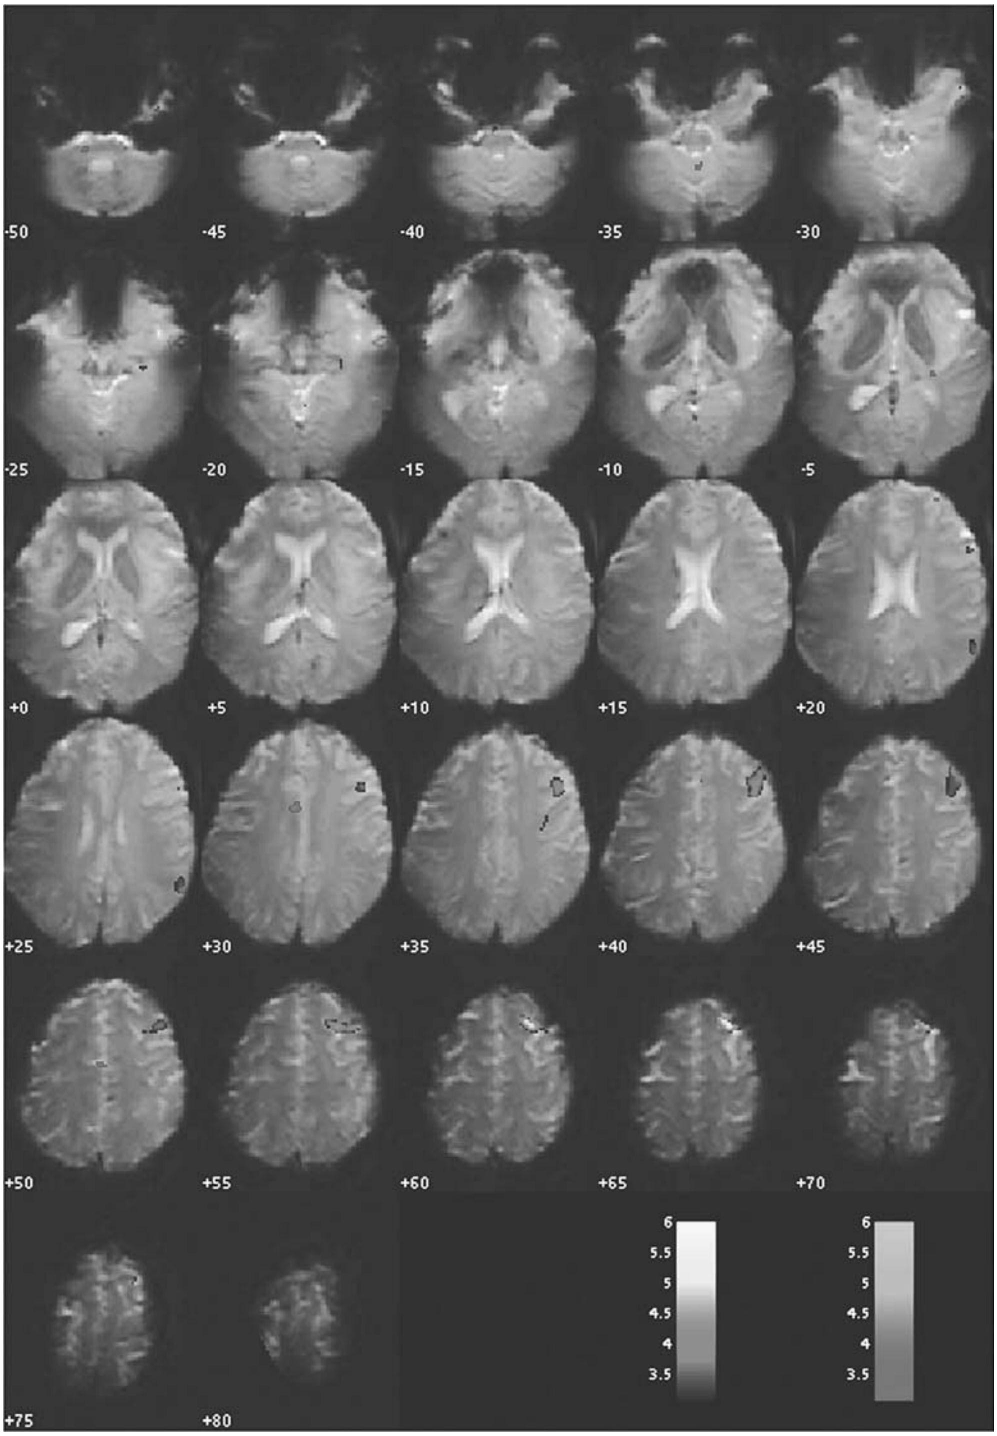

Fig. 10. This figure shows the analysis of an fMRI/EEG study in a 39-year-old woman with refractory partial seizures, arising from a small dysplastic lesion in the right frontal lobe. The figure shows positive BOLD response associated with six interictal discharges, captured during 35 min of fMRI acquisition. The fMRI analysis was performed using SPM99. The areas of activation are shown in warm colors, and the areas of deactivation in cold colors. The threshold was set at $p = 0.001$, uncorrected for multiple comparisons. There is a focal signal increase in the right frontal lobe in close proximity to the suspected seizure focus. Note: Here the subject's left is displayed on the image left (i.e. neurological convention). (See also Plate 87 on page XV in the Color Plate Section.)

in children younger than 6 years (although we have occasionally successfully performed fMRI in 5-year-olds), or in the severely ill or disabled patient. If applied and interpreted correctly, fMRI has the great promise to further improve our knowledge of the function of the human brain, by many applications in brain research. It is beginning to simplify patient investigation and monitoring, and in some centers is already replacing some of the more invasive investigation techniques.

Abbreviations

fMRI, functional magnetic resonance imaging; BOLD, blood oxygenation level dependent; EPI, echo planar imaging; SNR, signal-to-noise ratio; HDR, hemodynamic response function; ISI, inter-stimulus interval; TR, repetition time; FWHM, full width at half maximum; SPM, statistical parametric mapping; OLR, orthographic lexical retrieval; NVG, noun–verb generation.

List of Abbreviations

BPH	Benign prostatic hyperplasis
DCIS	Ductal carcinoma *in situ*
FNAB	Fine needle aspiration biopsy
GBM	Glioblastoma multiforme
HCA	Hierarchical cluster analysis
^{1}H MRS	Proton magnetic resonance spectroscopy
HPLC	High pressure liquid chromatography
(HR)MAS	(High resolution) Magic angle spinning
NAA	N-acetyl aspartate
PA	Polyamines
PC	Phosphocholine
PCA	Principal component analysis
PTC	Phosphatidylcholine
SCS	Statistical classification strategy
SSB	Spinning side bands

Introduction

Over the last two decades, a large body of *ex vivo* work and some *in vivo* work has demonstrated the utility of proton magnetic resonance spectroscopy (^{1}H MRS) in detecting and monitoring cellular chemical alterations associated with the development and progression of human malignant diseases [1–3]. Reports of conventional *ex vivo* ^{1}H MRS studies of human tissues, i.e. analysis of intact tissues with liquid-state MRS probes, have demonstrated that diagnosis, and for some organs, prognosis of malignant disease using metabolite ratios measured from spectra may reach 95% for both sensitivity and specificity. The accuracy can further be improved using an objective pattern recognition technique, statistical classification strategy (SCS) [2]. While tissue conventional MRS is fast and has shown the ability to diagnose accurately various human malignancies, it is limited by poor spectral resolution caused by the magnetic susceptibility effects of heterogeneous structures of the sample, and therefore detailed identification of individual metabolites is difficult. Metabolite profiling involving the measurement and quantification of tissue metabolites [4] is of increasing interest in the era of genomics and proteomics due to the direct involvement of tissue metabolites in tumor development and progression. High-resolution magic angle spinning (HRMAS) was developed to improve the spectral resolution of MR spectra of intact tissue by the reduction of susceptibility induced broadening such that individual metabolites may be identified and correlated with disease states.

Characterization of Human Malignancies

A malignant lesion exhibits unregulated growth characteristics both at primary and secondary (metastatic) sites. Initial attempts to characterize and understand tumor development and progression hinged therefore on lesion morphology and, as such, on histopathology using the light microscope, which has been the medical diagnostic “gold standard” for much of the 20th century. With the discovery of DNA and the advent of molecular genetics it became evident that tumor morphology represented only a single variable in the characterization of malignancies and could not report on risk factors or on the biological potential of a lesion. Predicting tumor behavior is essential for determining optimal disease management protocols and it is proteomics and spectroscopic metabolite profiling that have the potential to provide the information necessary for this endeavor. Metabolite profiling data, thus far, has been generated predominantly by studies involving MR spectroscopy and mass-spectrometry.

Specific Limitations of Histopathology

The principal limitation of histopathology is the restricted range of morphological changes that tissues can express. Pathologists attempt to extract a sophisticated pattern specific for an individual disease process from a continuum of morphological changes. These patterns overlap,

Graham A. Webb (ed.), Modern Magnetic Resonance, 1051–1064.
© 2008 *Springer.*

are susceptible to subjective assessment, and may be altered by sampling error. Patient assessment involves histological grading and clinicopathological staging. Tumor grading attempts to establish the aggressiveness of the tumor based on the degree of differentiation, or anaplasia, of tumor cells. However, such a distinction is subjective and often inconclusive. Staging of cancer determines the extent and spread of the disease, but it is unable to distinguish between recent but aggressive primary tumors and older but more slowly growing ones since clinical presentation of patients does not usually reveal how long a neoplasm has been present. Adequate staging of disease is often problematic. For instance, histopathological assessment of lymph nodes is subject to observer and sampling errors due to the large volumes of tissue to be assessed and the time and resource constraints that prevent thorough and complete examination. A retrospective study revealed that: "Serial sectioning of lymph nodes judged to be disease-free after routine examination revealed micrometastases in an additional 83 (9%) of 921 breast cancer subjects" [5].

Current histopathology has shown both conceptual and procedural inadequacies in providing optimal medical diagnosis. The development of new modalities capable of improving the accuracy of disease diagnosis is needed.

Cancer Pathology Determined by Conventional ^{1}H MRS

Conventional MRS measures cellular chemicals that are mobile on the MR time scale and their variations with changes in physiological or pathological function [6]. Although restricted by achievable spectral resolutions due to susceptibility induced broadening of resonances, many promising results have been obtained from conventional proton MRS studies of human malignant tissue and fine needle aspiration biopsies. The potential for diagnoses of malignant diseases in many organs has been demonstrated and more importantly, metabolic changes have been reported that were not morphologically manifested [7,8]. A study of aspiration biopsies from primary breast tumors not only determined diagnosis, but also reported on nodal involvement and tumor vascularization [9]. The sensitivity of MRS was demonstrated in a study using a rat model for lymph node metastasis where malignant cells in lymph nodes were detected with a greater sensitivity than histology. Micrometastases were detected that were not apparent even when the entire node was serially sectioned for examination by histology. The MR diagnoses were confirmed to be correct by xenografting nodal tissue into nude mice [10].

Historically, the limitation in spectral resolution of conventional proton MRS of tissue samples was realized as an obstacle to the identification of detailed cellular metabolism. A number of procedures, including sample packing and chemical extraction of tissue were investigated as ways to improve spectral resolution [11]. While solutions of tissue extracts did produce high-resolution spectra, the process was destructive and was found to alter the spectroscopic results to an unknown degree, depending on the procedure used and the thoroughness of extraction. Therefore, neither broad-line tissue analyses nor high-resolution measurements of extracts have been able to successfully evaluate malignant disease or exemplify the advantages of proton MRS in metabolite identification.

Methodology

Limited spectral resolution is a common problem in solid-state MRS for which many techniques have been proposed and tested. Among these magic angle spinning (MAS), a line-narrowing technique, was invented after the realization of the angle-dependent characteristics of the so-called "solid effects" that broaden the resonance lines [12,13]. These "effects" classically include dipolar coupling and chemical shift anisotropy, which always exist in solids. It was later shown that MAS could also reduce resonance line-broadenings caused by bulk magnetic susceptibility [14]. Specifically, in solids, spectral broadening due to these effects follows $(3\cos^2\theta - 1)$, where θ is the angle between the static magnetic field and the internuclear vector. Therefore, if a sample is spun mechanically at the "magic angle ($54°44'$, i.e. $3\cos^2(54°44') - 1 = 0$)," and at a rate faster than the broadening originating from these effects, the contribution of these effects to the spectral broadening can be reduced [15].

The HRMAS Method

The term HRMAS is currently used to refer to proton MRS of non-solution samples, such as biological tissues and cells, obtained with the application of MAS. It is important to note, however, that there are conceptual differences between classical MAS and tissue HRMAS used with proton spectroscopy [16]. The targets of MAS in classical proton solid-state studies are chemical shift anisotropies and dipolar couplings that are in ordinary solids >50 kHz. The application of MAS in solid-state studies has involved the use of high spinning rates and strong radio-frequency pulses in an attempt to decouple these homonuclear interactions. This is not the case, however, for the MAS study of cellular metabolites in biological tissues. Here, water-soluble molecules reside in the cytoplasm wherein their motion is restricted by magnetic susceptibilities caused by various interfaces with other cell structures and by inherent viscosity. Although classical "solid-effects" exist, for instance within cell membranes, they would contribute only to an almost invisible spectral background that is too broad (~50 kHz) to be measurable in a typical HRMAS spectrum of metabolites (~5 kHz, or 10 ppm on a 500 MHz spectrometer). Overall, the magnitude of line-broadenings due to magnetic susceptibility is approximately 10^3 less than that caused by "solid-effects," and can be greatly reduced by MAS.

Experimental

Sample Preparation

Fresh and previously frozen samples may be measured directly with HRMAS MRS [17–21]. For the purpose of preserving the metabolite concentrations within tissues, samples should not be collected or stored in any liquid medium. In cases where the size of frozen tissue exceeds the sample size required for HRMAS MRS analysis, samples must be cut on a frozen surface to avoid multiple freezing and thawing. Such a surface can be made with a thin metal plate, covered with gauze and placed on top of dry ice.

Tissue samples may be washed briefly with D_2O prior to spectroscopy if they contain visible amounts of blood. However, exposure to D_2O should be brief to minimize the possible loss of cellular metabolites [22]. We have observed complete depletion of metabolites for human prostate samples (~10 mg blocks) submerged in ~2 ml D_2O for approximately 10 min.

As always, when working with human materials of potential biohazard, universal precautions need to be practiced at all times. In particular, tissue samples will undergo spinning and even at "slow spinning speeds" of less than 1 kHz, tissue fluid can leak from the rotor cap if the cap is not in tight-fit with the rotor (Figure 1). Thus the compatibility and seal between rotor and cap should be tested using a D_2O solution prior to tissue analysis. The test can be done by comparing the weights of the rotor with solution before and after HRMAS using the same experimental conditions (temperature and spinning speed) used for tissue analysis.

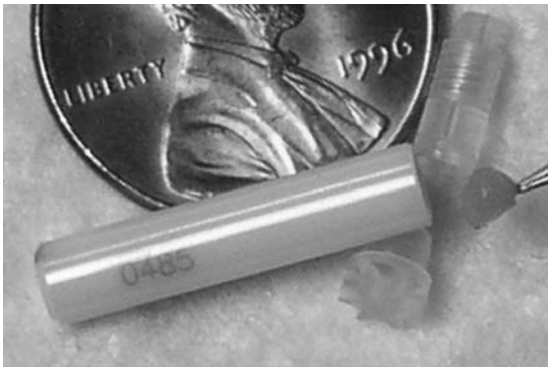

Fig. 1. Photograph of the rotor and a typical biopsy tissue sample that will be placed in the rotor using the tweezers for HRMAS MRS analysis.

To maximize spectral resolution, tissue samples should be limited to the physical boundaries of the receiving coils; for example by using Kel-F inserts to create a spherical sample when measuring samples on a Bruker spectrometer (Bruker BioSpin Corp., Billerica, MA). The use of a spherical sample is recommended for it minimizes shimming efforts as well as reduces the effect of the magnetic field inhomogeneity on the broadening of spectral lines.

Spectrometer Settings

Before tissue measurements, the HRMAS probe should be adjusted for its magic angle with potassium bromine (KBr) following the manufacturer's protocol for solid-state MRS. Ideally, measurements should be made at a low temperature (e.g. 4 °C) to reduce tissue degradation during acquisition.

The optimal spinning rate should be decided after consideration of several factors, including tissue type, metabolites of interest, and the plan for the tissue after HRMAS MRS analysis. Generally, the higher the spinning rate, up to 10 KHz as reported in the literature, the better the spectral resolution [23]. However, since high spinning rates can function as a centrifuge that can potentially disrupt tissue structures, if subsequent histopathological evaluation of the tissue is critical to the study, spinning rates must be reduced to limit any structural damage of the tissue that may interfere with histopathology. It is important to note that different tissue types endure different levels of stress. For instance, for the same spinning rate, skin tissue may be perfectly preserved in structure, while brain tissue can be completely destroyed. On the other hand, if less mobile metabolites such as lipids are the focus of HRMAS MRS evaluation, faster spinning rates may be necessary. The preservation of tissue architectures during HRMAS MRS is often critical and, as such, a number of studies have explored HRMAS MRS tissue analysis using moderate to slow spinning conditions [24–27]. These studies aimed to suppress spinning side bands (SSB) that overlapped with metabolite spectral regions of interest, using spinning rates that were not fast enough to "push" the 1st SSB beyond these regions. Interested readers should test these reported techniques for applicability to their specific tissue systems.

Optimal probe shimming is another critical factor that directly affects achievable spectral resolution. We have found that shimming on the lock or tissue water signal was not as sensitive as shimming on the splitting of the lactate doublet at 1.33 ppm, which fortunately presents in most excised biological tissues. However, in order to shim interactively on the degree of splitting, it is necessary to work with the frequency domain. This should not present a challenge to most current spectrometers. Furthermore, it should be possible to establish autoshimming protocols based on this criterion.

It is now accepted that malignancy related cellular marker metabolites may not present simply as present or absent, but rather as continuous changes in intensity throughout disease development and progression. Quantification of these metabolites can be extremely important if they are to accurately diagnose and characterize stages of disease. Metabolite concentrations may be estimated from HRMAS MR spectra by using either the intensity of tissue water signals or an external standard (e.g. a small piece of silicone rubber) permanently attached to the inside of the rotor or attached to the rotor inserts. Such an external standard can be calibrated with known compounds of known concentrations. Interested readers can make such compounds by dissolving known amounts of relevant metabolites in agarose gel.

HRMAS MR spectra may be acquired with or without water suppression, depending on whether water intensities are required for the estimation of metabolite concentrations. A rotor-synchronized CPMG sequence may be applied to achieve a flat spectral baseline if there are undesired broad resonances from the probe background.

Histopathology

The clinical utility of high-resolution tissue metabolite profiles obtained with HRMAS MRS needs to be investigated and validated by means of accurate and detailed correlation with serial-section tissue pathologies. Such correlations are particularly important for studies of human malignancies due to the heterogeneity that may be inherent in the disease. Tissue pathology can vary greatly from region to region within a single tumor, and intertumor differences may be even more pronounced. An obvious advantage of HRMAS MRS is its preservation of tissue for subsequent histopathological analyses, allowing the establishment of correlations between metabolite profiles and quantitative pathologies [28–30].

Routine clinical histopathology data is most often inadequate. Routine histopathology, in particular 5 micron slices of the tissue biopsy, provides information about the presence or absence of certain features. These features may vary from slice to slice and therefore information from a small percentage of the tissue may not correlate with the spectral profile, which consists of the weighted sum of the profiles from all tissue slices or indeed the entire piece of tissue. Hence, for certain types of tissues, particularly neoplasm samples with known heterogeneities, histopathology needs to be evaluated quantitatively. This can be achieved laboriously by the histopathologist's examining serially sectioned tissue slices or possibly with the assistance of computer image analysis of these same sections. The sectioning frequency differs with tissue type and should be determined in consultation with the pathologist. For instance, the optimal sectioning frequency for human prostate was found to be between 200 ∼ 400 μm.

Data Analysis

Histopathological analysis in cancer diagnosis relies on the observation of variations in colors and shapes using a light microscope. Importantly, to suspect disease the pathologist must observe widespread rather than isolated changes in color and/or shape, a process requiring keen pattern recognition. Similarly, pattern recognition methods are most often required to allow the diagnosis of malignancy from MRS tissue metabolite profiles. Development and progression of malignant disease involves the simultaneous evolution of many metabolic processes. Therefore, although some individual metabolites have been reported to correlate with disease types and stages [1,2] it is more likely that the overall metabolite profile rather than changes in single metabolites will be sensitive and specific for disease diagnosis [31,32]. Sophisticated statistical classification strategies (SCS) have been developed and applied to the analysis of conventional MRS of malignant tissues [33]. To date, however, principal component analysis (PCA) using readily available statistical programs has been sufficient for revealing accurate diagnostic information from HRMAS MRS data [34,35]. However, the application of SCS may further improve these accuracies.

HRMAS MRS of Human Surgical Specimens

Over recent years, HRMAS MRS has been applied biomedically to the analysis of human surgical samples, research animal tissues, and cultured cells. The scope of the methodology presented in this section will be limited to HRMAS MRS studies of human tissues and will be presented where possible in context with preceding studies of the same tissues using conventional MRS. Although presented in this context, comparison of the sensitivities and specificities obtained using conventional and HRMAS MRS are not at this stage warranted as unlike the mature discipline of conventional MRS, HRMAS MRS is still in its infancy and has reported only studies with restricted patient numbers. Although the capability of HRMAS has been clearly demonstrated in generating high-resolution spectra from which individual metabolites can be measured and such measurements were impossible with conventional methods, studies of large patient populations, as with conventional MRS studies, that allow evaluation of the sensitivity and specificity of the method have not yet appeared in literature. Similarly, it is not as yet possible to provide the reader with one concise and optimal method for undertaking HRMAS MRS. Detailed methods are provided for each of the studies presented and these methods discussed in terms of the study aims. In an emerging discipline such as HRMAS MRS care must be taken to rigorously address methodological variables with respect to the type of tissue being analyzed and the specific information required. Increased spectral quality will most often be obtained with higher spinning speeds but this will be at the expense of tissue preservation allowing subsequent histopathological assessment of the tissue. Some tissues are less easily destroyed than others by high spinning speeds and thus preliminary experiments need to be undertaken to determine optimal parameters.

MRS analyses on tissue extracts have been studied for many years on many diseases, and have formed a large body of literature. Results from these studies are worthy of close examination and review but will not, however, be included in this review due to the following: the pathology of the tissue samples most often remains incomplete and/or the degree of extraction cannot be certain.

Brain

Human brain was the first study reported using proton HRMAS MRS to determine tissue pathology. Due to the relative motion stability and homogeneity compared to other organs, brain has dominated the development of *in vivo* MRS, and accordingly has inspired many *ex vivo* studies, primarily including neurodegenerative diseases and tumors, aimed at understanding metabolism and defining brain tissue chemistry.

The first HRMAS MRS human studies on brain tissues from autopsies described semi-quantitative evaluation of the pathology of a neurodegenerative disease, specifically Pick disease [36]. Through MRS measurements and traditional neurohistopathology, direct and semi-quantitative correlations were found to exist between the levels of N-acetyl aspartate (NAA) and the amount of surviving neurons in varying regions of examined brain as seen in Figure 2. The study also, for the first time, demonstrated that the spectral resolution of HRMAS proton MRS was comparable with that measurable with conventional proton MRS of tissue

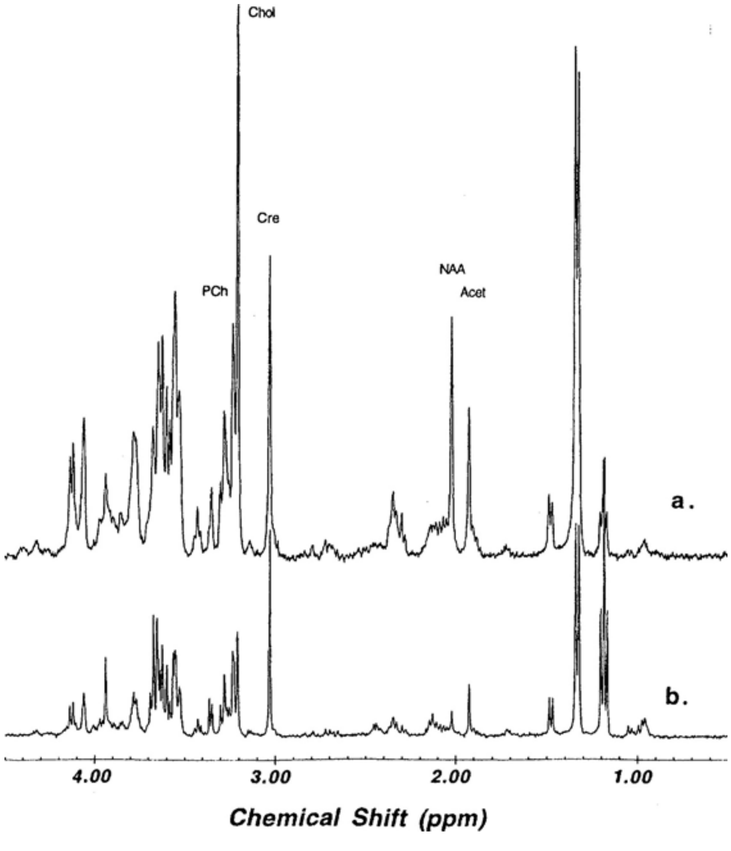

Fig. 2. Comparison of HRMAS MR spectra of brain tissue from the relatively unaffected primary visual cortex region (a) and the severely Pick disease affected rostral inferior temporal gyrus region (b), showing a marked decrease in NAA concentration, 8.48 μmol/g for spectrum a and 4.96 μmol/g for spectrum b. This decrease in NAA was found to correlate with an average neuronal count decrease of 33 neurons per 0.454 mm^2. The spectra were acquired at 2 °C, and were scaled according to concentration of creatine at 3.03 ppm for enhanced visualization. *Figure 4 from ref. [36]*

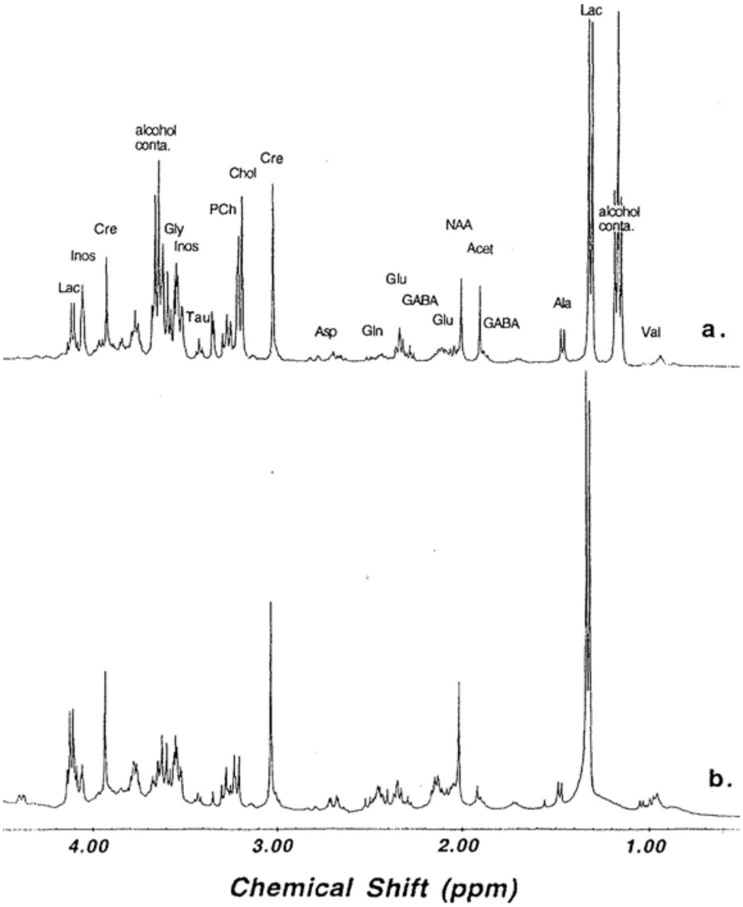

Fig. 3. Comparison of human brain proton MRS acquired with (a) HRMAS on intact tissue and (b) conventional method on extract solution. The spectral resolution was comparable while relative intensities for certain metabolites varied.

extracts (Figure 3), and superior to that obtained using conventional MRS of intact tissue (Figure 4). Another early study, also on autopsy brain tissues, correlated MRS data and stereological pathology for Alzheimer's disease and confirmed NAA concentration to be proportional to neuronal density (Figure 5). In this study, 7 human brains were examined, 3 of which were Alzheimer diseased and 4 which presented as normal human control brains. Figure 5 demonstrates the quantitative nature of the NAA and neuronal count relationship, as the correlation intercepted at zero (–0.29 ± 1.15 μmol/g) [37].

The MRS study of brain tumor intact tissues using conventional MRS suggested the diagnostic importance of lipid and lipid metabolites. Kuesel and colleagues reported correlations between MR lipid signal intensities and the amount of necrosis in astrocytomas [38]. With 42 cases, they showed that the intensity of the mobile fatty acyl –CH=CH- resonance at 5.3 ppm, differentiated 0, 1–5 and 10–40% of necrosis with statistical significance [39]. These results represented a great potential use for *ex vivo* MRS for astrocytoma diagnosis, in particular for differentiating Grade III and Grade IV tumors, which have radically different prognoses. The technique also ensured that necrotic foci often missed by clinical pathology were identified. Working with conventional MR spectra of brain tumor tissues, Rutter *et al.* attempted to categorize tumors according to 1D peak ratios (3.1–3.4 vs. 1.1–1.5 ppm), T_2 values of peaks at 1.3 ppm and cross-peaks on 2D COSY spectra (0.9 ppm with 1.35 ppm, representing methyl-methylene couplings; and 1.3 ppm with 2.05 ppm for couplings between methylene groups in fatty acids) [40]. With 38 samples studied from 33 subjects (including normal tissue, astrocytoma, GBM, meningiomas, and metastases), they were able to use peak ratios to

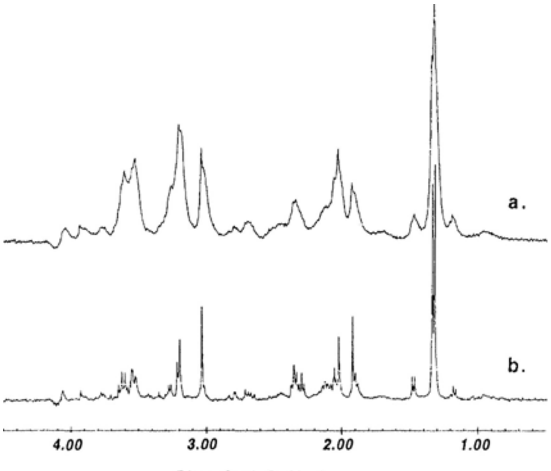

Fig. 4. Comparison of human brain proton MRS acquired with (a) conventional MRS and (b) HRMAS MRS. *Figure 2 from ref. [36].*

differentiate GBM from astrocytomas and normal tissues. They also found that the T_2 of the 1.3 ppm peak could be fitted by a double exponential function and that the long fraction of T_2 values could be used to group both GBM and metastasis from normal tissue. However, tissue spectra measured with conventional method of low resolution prevented these studies from observation of individual brain metabolites other than identification of broad lipid peaks.

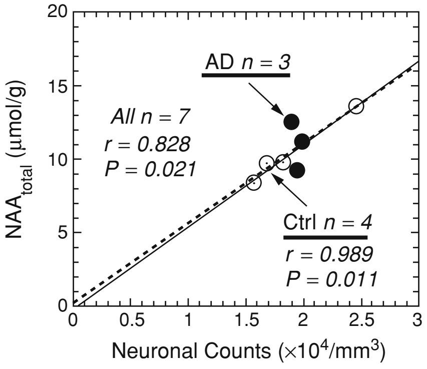

Fig. 5. A statistically significant linear correlation was found to exist between the number of neurons and the concentration of $\mathrm{NAA_{total}}$, measured from 3 Alzheimer diseased and 4 normal control brains (the dotted line, $r = 0.828$, $P = 0.021$). The solid line represents the linear correlation obtained when only normal control brains were included ($r = 0.989$, $P = 0.011$). *Figure 3 from ref. [37].*

HRMAS MRS of brain tumors allowed for the first-time detailed profiles of water-soluble metabolites and lipids to be obtained from the same spectra [31]. In a study of 19 brain tumors, including astrocytomas, GBM, meningiomas, Schwannomas, and normal brain, metabolite concentrations both in absolute units and relative ratios normalized to the creatine resonance at 3.03 ppm were reported and T_2 values for these metabolites were measured *ex vivo* for the first time (Table 1). Metabolite concentrations from intact tissues and tissue extracts from the same tumors were compared to each other and to the literature values. While the concentrations for some metabolites, measured by HRMAS MRS, were similar to those in extracts, others showed much higher concentrations in tissue than in extracts. Metabolite concentrations and T_2 values accurately differentiated tumor types based on clinical data, but detailed histopathology of the tissue samples was not performed due to the false belief at the time that HRMAS MRS damaged tissue such that subsequent histopathological analysis was not possible.

The important fact that accurate histopathological evaluation of tissue samples after HRMAS MRS is possible and the necessity of performing quantitative pathology on the same tissues after MRS was reported by Dr. Anthony and colleagues [28]. Tissue pathologies from both HRMAS MRS analyzed tissue and adjacent tissue that had not undergone HRMAS MRS before histopathological evaluation were analyzed semi-quantitatively for each region of the brain tumor. The quantitative histopathological data obtained from the study showed that adjacent specimens from the same tumor region shared similar histopathological features. Although quantitative differences were noted, these differences were most likely due to extensive tumor microheterogeity and not the result of the HRMAS MRS procedure. Futhermore, correlations between the amount of tumor necrosis and the concentrations of mobile lipids ($R^2 = 0.961$, $p < 0.020$) and lactate ($R^2 = 0.939$, $p < 0.032$), as well as between the numbers of glioma cells and the ratio of phosphocholine (PC) to choline resonances ($R^2 = 0.936$, $p < 0.033$) were observed. The strong linear correlation between tissue necrosis (%area) and lipids (mM) indicated that the amount of tissue necrosis can be estimated using the measured concentration of lipids from HRMAS MRS, and that according to the long T_2s these lipids are relatively mobile consistent with them being products of cell membrane degradation. Additionally, the results of the correlation obtained between the number of glioma cells and the phospocholine to choline resonances suggested the importance of measuring and quantifying these two resonances separately, which is difficult with both *in vivo* and *ex vivo*

Table 1: Matrix of selected brain metabolite concentrations measured with HRMAS MRS for differentiation between different pathological specimens NAA, in the table, includes both measured resonances of NAA at 2.01ppm and acetate at 1.92 ppm (see text for details); Numbers in parentheses represent resonance chemical shift in ppm. The resonance at 3.93 is tentatively assigned to the Cr metabolite. As an example of the use of this matrix, the Chol resonance can be used to differentiate low-grade/anaplastic astrocytomas from GBMs with a significance of $p < 0.05$. Similarly, the glycine resonance (Gly) can be used to distinguish GBMs from Schwannomas with a $p < 0.005$

	Normal	LG and AA[a]	GBMs	Schwannomas	Meningiomas

[f] $p < 0.00005$, two-tailed student's t test.

conventional MRS methods, but readily achievable with MAS.

It is expected that HRMAS MR spectra of tissue rather than MRS of tissue extracts will provide metabolite information more closely related to that in the *in vivo* brain. However, cautions should be exercised when comparing *in vivo* MRS and HRMAS MRS data, as *in vivo* MRS will always be broad-line in nature. Nevertheless, a number of studies, both in adult [41] and pediatric [42] brain tumors, have concluded that there is good agreement between *in vivo* and *ex vivo* tissue MR spectra with high-resolution *ex vivo* results providing both insight into which metabolites reside within the broad resonances observed *in vivo* and a link between *in vivo* MRS evaluations and neuropathologies.

Prostate

The search for marker metabolites of prostate cancer has been inspired by the current state of prostate cancer pathology, wherein more than 70% of newly diagnosed cases are categorized with similar Gleason scores (6 or 7), but for which individual patient outcomes within these tumors are drastically different and unpredictable.

Hahn and colleagues reported the first intact prostate tissue conventional MRS study of 66 benign prostatic hyperplasia (BPH) and 21 prostate cancer samples from 50 patients [43]. They divided the proton spectral region between 0.5 and 3.55 ppm into 50 equal subregions, and applied multivariate linear-discriminant analysis to the point-reduced spectra. The study found six spectral regions including those containing citrate, glutamate, and taurine to be sensitive in differentiating BPH from cancer with an overall accuracy of 96.6%. This algorithm was tested by the same research group on another group of 140 samples from 35 patients after radiotherapy to test for the sensitivity of spectroscopy analysis in differentiating cancer positive vs. cancer negative samples [44]. After eliminating 24 samples that did not have sufficient signal-to-noise ratios, they reported, with the remaining 116 spectra, the sensitivity and specificity of tissue spectra in identifying cancer samples to be 88.9 and 92%, respectively.

Van der Graaf and colleagues presented another interesting study of intact prostate tissue combining conventional MRS and high-pressure liquid chromatography (HPLC) analysis to measure the relationship between polyamines (PA) and prostate cancer [45]. Although they observed PA in the proton spectra and measured statistically significant drops of PA in cancer samples with HPLC, no correlation between PA levels measured by MRS and those determined by HPLC were presented for the same cases due to very limited number of samples analyzed. Nevertheless, the study suggested the existence

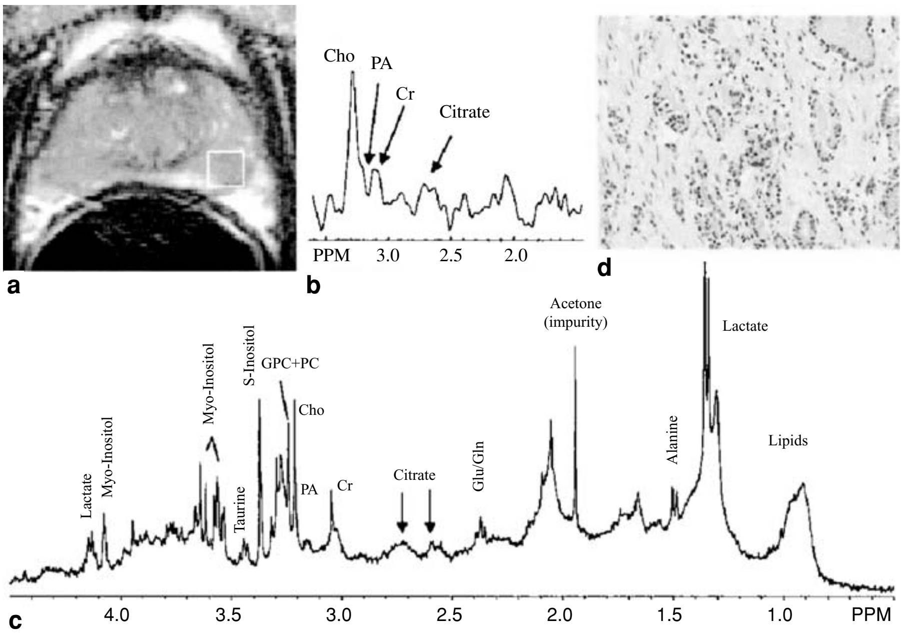

Fig. 6. Results from a presurgical 3D-MRSI of a 56-year-old prostate cancer patient were concordant with histopathologically classified malignancy of H and E stained tissue samples of excised tissue with Gleason 3 + 4 prostate cancer, **d**. Spectrum **b**, shows elevated levels of choline and low levels of citrate and polyamines relative to creatine in the 0.24 cm3 voxel of **a**. The postsurgical HRMAS MR spectrum (c) confirms the 3D-MRSI results with enhanced resolution that also identifies elevated levels of GPC + PC relative to choline. *Figure 2 from ref. [30].* (See also Plate 88 on page XVI in the Color Plate Section.)

of a potential prostate biomarker that MRS may be able to quantify, as well as a direction for future studies. More recently, Mountford *et al.* reported a conventional MRS study of 71 prostate samples from 41 patients who underwent both cancer and non-cancer prostate surgeries [46]. By using peak ratios 3.2/3.0 ppm (choline-to-creatine) and 1.3/1.7 ppm (lipid-to-lysine), they were able to differentiate malignant from benign tissues with 97% sensitivity and 88% specificity.

Tomlins and colleagues experimented with proton HRMAS MRS analysis on human prostate tissues with both 1D and 2D MR spectroscopy. In their qualitative report, they confirmed the usefulness of HRMAS MRS in producing high-resolution spectra from intact human prostate tissues [47]. A second HRMAS MRS study of human prostate tissues from 16 patients was the first to include quantitative pathology on the MRS specimens and to include multiple subjects [29]. The results of the study proved the validity of HRMAS MRS for the accurate determination of tissue histopathology. Both citrate and spermine were quantified from the tissue HRMAS MR spectra and shown to be linearly correlated with the amounts of prostate normal epithelium. In 2003, Swanson and colleagues reported an interesting study of HRMAS MRS of tissues from 26 patients harvested post surgically under the guidance of 3D-MRSI from lesions that had been analyzed using *in vivo* MRS prior to prostatectomy. Figure 6 shows the resulting spectra from a 56-year-old prostate cancer patient [30]. By combining the MRS results with quantitative pathology of the same tissue after spectroscopy, metabolite discriminators (i.e. ratios of citrate, polyamine, and choline compounds to creatine) were found to differentiate normal prostate epithelial tissue from cancer and stromal tissue. Furthermore, a correlation between the intensity of MIB-1 immunohistochemical staining and the ratio of choline to creatine resonances was reported, supporting their findings *in vivo*. These results were dependent on the assumption that the creatine concentration did not alter during the disease process, which awaits verification.

Breast

Human breast tissue was difficult to analyze using conventional proton MRS due to high lipid content. As pioneers of this work, Mountford and colleagues noted that to acquire a spectrum that was diagnostically meaningful, fine-needle aspiration biopsy (FNAB) instead of regular tissue samples had to be utilized [48]. In a study of 218 FNAB samples from 191 patients with benign lesions, ductal carcinoma *in situ* (DCIS), and invasive carcinoma, they found that by using the resonance peak height ratio threshold of 1.7 (3.25 vs. 3.05 ppm; or choline-compounds vs. creatine), benign lesions could be differentiated from carcinoma with 95% sensitivity and 96% specificity. However, this single ratio identifier only worked if the signal-to-noise ratio, particularly for choline peaks at 3.25 ppm, was above 10. To extend the MRS differentiation capability below this limit, and more importantly to search for a more robust diagnostic protocol of computerized spectral analysis, Mountford *et al.*, along with Smith *et al.* at the NRC, Canada, used a pattern recognition method, SCS, developed to utilize the entire MR spectrum instead of only the aforementioned two peaks for the purpose of analysis [9]. From measurements conducted on 140 samples, they reported an overall accuracy of 93% in distinguishing benign from malignant tumors using SCS. Furthermore, they reported that using SCS classifiers, lymph node involvement and tumor vascular invasion could be predicted with 95 and 94% overall accuracies, respectively. The advantage of SCS in relating proton FNAB spectra with breast cancer diagnosis and possibly prognosis is evident and its potential in clinical usage is apparent. However, the more advanced the SCS, the less evident were the direct connections with individual metabolites.

HRMAS MRS overcame many of the limitations of conventional MRS32. Even with such lipid-rich tissue, HRMAS MRS successfully produced high-resolution proton spectra. Results from a study at 400 MHz of 19 cases of ductal carcinomas showed that both the high fat contents and individual cellular metabolites could be measured from the same spectrum. Particularly, from these spectra, PC could be quantified separately from choline; and the ratio between PC and choline was found to correlate with tumor grades, as shown in Figure 7.

A more recent detailed HRMAS MRS study at 600 MHz of 10 ductal carcinomas by Sitter *et al.* compared HRMAS MR spectra with those obtained using conventional MRS of perchloric acid tissue extracts [20]. The study concluded that for breast tissue, HRMAS MRS was able to achieve spectral resolutions approaching those obtained using conventional MRS of extracts. 2D J-resolved and COSY MRS was used to accurately assign metabolites.

Cervix

Mountford and colleagues began analysis of human cervical biopsies with conventional proton MRS in the early 1990s [49]. Broad-line resonances at 0.9 ppm (CH3), 1.3 ppm (CH2), and 3.8–4.2 ppm (CH) were found to distinguish invasive from pre-invasive epithelial malignancy [50].

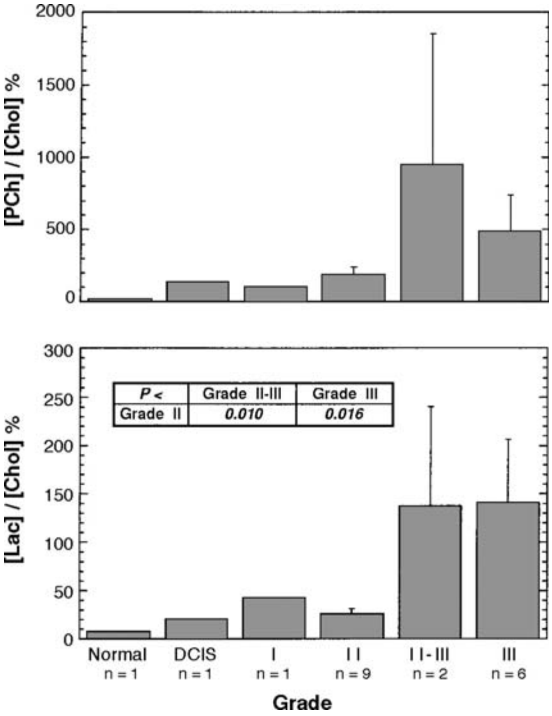

Fig. 7. Examples of observed correlations between histopathological grades of breast ductal carcinomas and the means for metabolic intensities, particularly PC over choline (A) and lactate over choline (B) measured with HRMAS MRS. Of note, the HRMAS method provided a means to differentiate PC from choline in the such a lipid-rich tissue. *Figure 4 from ref. [32].*

More recently, Sitter and colleagues reported the use of HRMAS MRS of cervical tissue from eight cancer and eight non-cancer patients [.35]. In addition to their presentation of detailed resonance assignments for cervical metabolites, they were able to use PCA to separate cancer from non-cancer samples with the first principal component (PC1). This principal component was comprised primarily of lactate, the methyl, and methylene groups of lipids, and, to a lesser extent, the choline-containing compounds. This component represented 63% of the variations in the spectra.

Kidney

HRMAS MRS analysis of kidney tissue has been shown to diagnose renal cell carcinoma based on an increased intensity of lipid resonances in malignant compared to

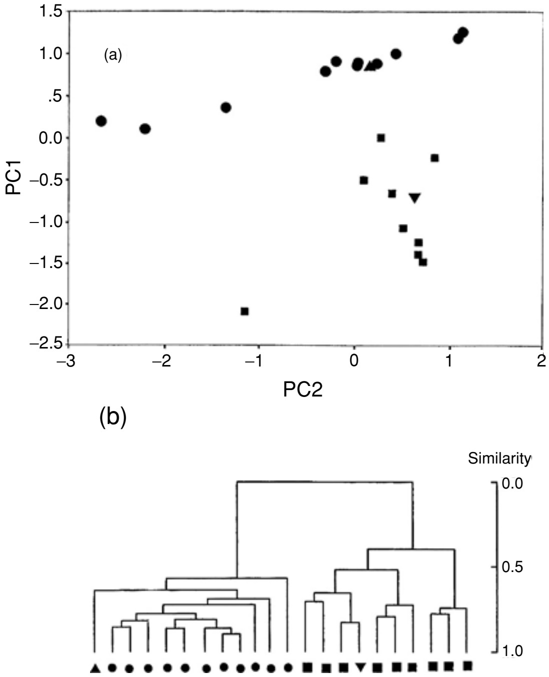

Fig. 8. Using PCA (a) and HCA (b), tumor samples can be differentiated from non-tumor samples. Key: (•) normal tissue; (■) renal cell carcinoma; (▲) sample from bladder metastasis in renal collecting duct; and (▼) lung metastasis in renal cortex. *Figure 3 from ref. [.35].*

control tissues [51,52]. These studies were not designed to test the utility of HRMAS MRS in the diagnosis of renal cell carcinoma, but rather to illustrate the feasibility of HRMAS MRS for assignment of resonances and identification of metabolites as well as to develop two-dimensional HRMAS MRS techniques for the assessment of intact tissues.

Later, a study of 22 paired control and tumor samples of human renal cortex used computer-based pattern recognition techniques to show that using PCA and hierarchical cluster analysis (HCA), tumor samples were differentiated from non-tumor samples, as shown in Figure 8 [34].

Sarcoma

HRMAS MRS has been shown to be a useful technique in the analysis of human sarcoma tissue. Singer and colleagues reported a comparison of 2D TOCSY spectra with and without HRMAS MRS, which demonstrated the superior resolution of the MAS technique by revealing less intense cross peaks that were not observed when the sample was not spun [53,54]. For this initial study, spectra of liposarcoma and lipoma were dominated by signals from lipids, interfering with the ability to observe resonances from other metabolites. More recently, Chen and colleagues have developed a double pulsed field gradient selective echo (DPFGSE) technique in combination with HRMAS MRS to selectively excite spectral regions that contain less abundant non-lipid metabolites [23]. With their new technique they were able to observe and quantify phosphatidylcholine (PTC), PC and choline, and found, using six paired samples from six patients, that the ratio of PTC/PC differentiated normal fat from lipoma-like well-differentiated liposarcoma with statistical significance ($p < 0.001$).

Lymph Nodes

Accurate detection of metastatic deposits in lymph nodes is often the most important predictor of cancer patient prognosis. Histopathology is subject to sampling and observer error and thus there is a real need for a new, rapid, and cost-effective method with high accuracy for this purpose.

An early study identifying malignant cells in lymph node tissue using 1D ^{1}H MRS was limited by high fat content of the tissue and the low spectral resolution obtained. Two-dimensional (2D) techniques successfully resolved resonances and allowed the complex spectra from lymph nodes to be assigned and correlated with detailed histopathology [10]. Choline and lactate were found to be key metabolites diagnostic of the presence of metastases in lymph nodes using the 2D method. However, these 2D MR experiments require long acquisition times (4–5 h) during which sample degradation may occur, potentially compromising the outcome of the measurement. In addition, conventional 1D and 2D techniques cannot address the problem of resonance broadening directly and thus useful diagnostic information may be missed.

Alternatively, MRS of FNAB of lymph node tissues has been used to diagnose the presence of metastases in lymph nodes from melanoma patients [55]. Spectra of node tissue containing metastatic melanoma were characterized by the presence of a distinct resonance from choline-containing metabolites at 3.2 ppm. The ratio of the integrals of resonances from lipid and metabolites (1.8–2.5 ppm region) and "choline" (3.1–3.3 ppm region) distinguished benign nodes (38.8 ± 34.3) from melanoma containing nodes (7.2 ± 6.8) with $p < 0.012$ (separate t-test) [55]. This method assumes the chemistry of the node detectable by MRS changes immediately upon the node being infiltrated by metastatic cells. This is supported by studies in a rat lymph node metastasis model where MRS detected the presence of malignant cells prior to clusters of metastatic cells being identified by histopathology.

Instead, single malignant cells were observed unclustered throughout the node, the presence of which was confirmed by growing these nodes in nude mice, which subsequently developed tumors. Datasets in the study of MRS on FNAB as a method of diagnosing lymph node metastases remain, however, small and until larger databases confirm these findings the possibility that the method introduces a sampling error cannot be excluded.

The application of HRMAS MRS to intact tissue analysis was in fact initiated from the proton MR detection of lymph node metastases in a rat model for breast cancer metastasis. Since then, HRMAS MRS has also been successfully applied to the proton MR analyses of human lymph nodes from breast cancer patients. Malignant nodes were distinguished from reactive nodes based on the peak height ratio of the smallest to largest peaks resolved in the 0.9 ppm resonance multiplied by the peak height ratio of the choline and creatine resonances at 3.2 and 3.0 ppm, respectively (Figure 9). Three of four axillary nodes from breast cancer patients that were clinically suspicious but diagnosed cancer free on routine histopathology had an HRMAS MRS ratio consistent with reactive nodes. The fourth node in this category was, by HRMAS MRS criteria, malignant. Review of the histology of these nodes using increased magnification and immunohistochemical staining identified malignancy in the fourth node missed during routine examination.

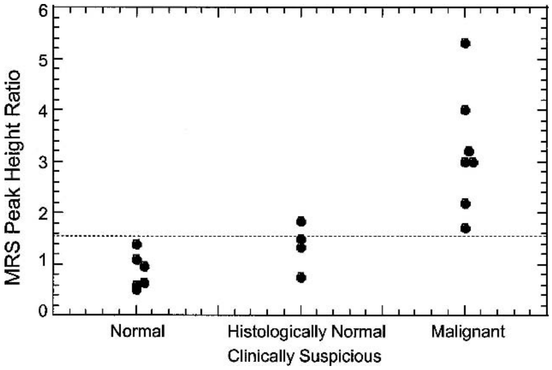

Fig. 9. HRMAS MRS of Human Lymph Nodes: Malignant nodes were distinguished from normal (reactive) nodes based on the MRS Peak Height Ratio (ratio of the smallest to largest peaks resolved in the 0.9 ppm resonance multiplied by the ratio of the choline and creatine resonances at 3.2 and 3.0 ppm). One of four axillary nodes that were clinically suspicious but cancer free on routine histopathology had an HRMAS MRS ratio consistent with malignancy. Review of the histology for all four nodes identified malignancy in this one node missed by routine histopathology.

Future Developments and Conclusions

The development of proton HRMAS MRS for tissue analysis has not only drastically simplified the procedure of obtaining high resolution cellular metabolite spectra directly from intact tissue, but more importantly allows quantitative pathology to be conducted on the same tissue after MRS measurements for correlation with individual metabolite concentrations or collective alterations in overall metabolite profiles. The high-resolution spectra generated by HRMAS MRS contain many more resonance peaks for analysis than conventional MRS. This greatly improves the likelihood that sophisticated data analysis methods can accurately distinguish between differing pathologies. However, the increased discriminatory power of the method relies on precise histopatholgical information about the tissue assessed by HRMAS MRS being available. This is only possible when detailed serial section histopathological methods are undertaken to substantially increase the precision of the information currently obtained from clinical pathology.

Glossary of Terms

Astrocytoma—The most common type of brain tumor in adults; astrocytomas, known for their marked potential for malignant progression and infiltrative nature, can be classified histopathologically into three grade of malignancy: WHO Grade II astrocytoma, WHO Grade III anaplastic astrocytoma, and WHO Grade IV GBM.

Benign Prostatic Hyperplasia—Enlargement of the prostate and more specifically, overgrowth of the epithelium and fibromuscular tissue of the transition zone and periurethral area.

Ductal Carcinoma *In Situ*—Noninfiltrative lesions composed of malignant epithelial cells that are confined to the mammary ducts and lobules.

Glioblastoma Multiforme—The most malignant grade of astrocytoma (WHO Grade IV), which has an overall survival time of less than 2 years for most patients. These tumors are histopathologically characterized according to their dense cellularity, high proliferative indices, endothelial proliferation, and most importantly the presence of focal tissue necrosis.

Lipoma—Commonly diagnosed benign tumors of adipose tissue that can develop anywhere in the body where fat is normally found.

Liposarcoma—A commonly diagnosed soft tissue sarcoma in adults which be found anywhere in the body and for which there exists several types with varying clinical outcomes.

Meningioma—Intracranial tumors that arise in the meninges and compress the underlying brain. In general, many of these tumors are benign, however, others are malignant with the capability to metastasize, both locally and distally.

Metabolite Profiling—The study of small molecules, such as lipids, peptides, amino acids, and carbohydrates, which represent steady-state concentrations of intermediate products or end products of cellular processes and as a result can be thought of as the ultimate response to genetic and environmental stimuli.

Necrosis—Tissue and/or cell death.

Neoplasm—Literally meaning "new growth." An abnormal growth of tissue which may be benign or malignant.

Oncogenomics—The study of genes, gene sequences, and the underlying genetic alterations that appear to be involved in oncological pathways.

Reactive Nodes—Lymph nodes that have been immunologically challenged.

Schwannoma—Benign tumors that arise on peripheral nerves in general and on cranial nerves in particular, especially on the vestibular portion of the eighth cranial nerve.

Sensitivity—The term relating to the percentage of people with disease who test positive for the disease, i.e. the percentage of patients with cancer who have positive biopsy results.

Specificity—The term referring to the percentage of people without disease who test negative for the disease, i.e. patients without cancer with cancer negative biopsy results.

Acknowledgments

The authors thank their former and present staff, students, and collaborators involved in the research presented in this review whom have all worked diligently towards developing MRS and HRMAS MRS for determining tissue pathology. We also thank our colleagues and friends from around the world for allowing us to describe their work and for their many interesting discussions and contributions to this review. Particular thanks to Carolyn Mountford, Peter Russell, and Peter Malycha for their encouragement and support. We thank Sinead Doran and Deborah Edward for helping prepare the manuscript. LLC and MAB acknowledge grant supports from PHS/NIH CA095624 and from DOD W81XWH-04-1-0190.

Contemporary neurosurgeons depend on precise lesion localization to maximize surgery and clinical outcome. Advances in neurosurgical technique and instrumentation evolved as surgical corridors became more precise. Magnetic resonance imaging (MRI) has considerably improved the diagnosis, treatment, and follow-up of patients with neurological disease. With the widespread use of MRI, it is difficult to conceive that, before the introduction of imaging technology, neurosurgery relied on precarious tools.

Historical Milestones in Neurology

Cranial trephination was used thousands of years ago by Neolithic man to liberate individuals thought to be possessed by evil spirits [1,2]. It resurfaced as a treatment for infantile convulsions and was still performed as late as the mid-19th century for both trauma and epilepsy [3]. Franz Joseph Gall proposed that intellectual faculties are highly compartmentalized in the brain and that examination of the surface of the skull reflects the extent to which an aptitude is developed [4]. The use of scientific evidence to determine cortical compartmentalization of function was first initiated by Paul Broca [5]. The development of imaging techniques began with the discovery of X-rays by Wilhelm Röntgen in 1895. In 1918, Walter Dandy made the serendipitous discovery of intraventricular air in a patient who had suffered cranial trauma [6]. This observation led to the development of pneumoencephalography (Figure 1) as a method for localizing intracranial pathology, based on ventricular displacement by cerebral mass lesions. A decade later, Moniz introduced cerebral angiography, a method still used to visualize vascular abnormalities [7]. Ultrasound was subsequently developed as a non-invasive method of localizing central nervous system (CNS) pathology [8]. Originating from ideas of Cormack [9] and Hounsfield [10], brain imaging was revolutionized in the mid-1970s by the invention of computerized tomography (CT). This discovery significantly enhanced diagnostic accuracy and improved surgical planning and outcome. The subsequent development of MRI by Lauterbur [11] and Mansfield [12] provided enhanced tissue contrast and remains the best imaging modality for diagnosis and determining the effect of treatment on both the lesion and the brain.

Principles of Intraoperative Imaging

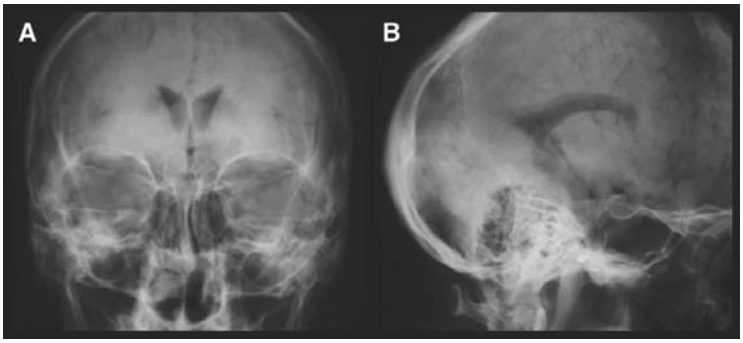
Intraoperative imaging allows acquisition of near real-time images in the operating room (OR). As surgery often disrupts the brain environment, acquiring instant images at any time during and after completion of the surgery represents a considerable advantage. CT imaging was introduced into the OR in 1982 [13]. The first report of intraoperative MRI (iMRI), by Black *et al.* was in 1997 [14]. The use of intraoperative CT declined following the introduction of iMRI, in part due to lower tissue contrast and image artifact due to surgery and instrumentation. MR technology confers non-invasive, radiation-free, multiplanar, real-time, high-resolution images of the nervous system. MRI systems that include magnets of $\geq$1.5 T and high performance gradients provide a unique method for the evaluation of diffusion and perfusion tensor imaging, as well as a way to assess brain function. Diffusion images measure the mobility of water molecules in tissue. As pathological states can disrupt barriers that normally restrict water motion, diffusion imaging reveals information about tissue integrity [15]. Perfusion images represent the rate at which blood is delivered to the tissue, and can therefore be used to identify areas displaying an increase or decrease in blood flow [16]. Functional MRI allows in a non-invasive way the precise identification of brain areas undergoing a sharp increase in oxygen supply induced by a certain cognitive process or task [17]. Essential components of an iMRI system are the magnet, gradients, radio frequency (RF) coil designs, the operating table, and the RF shielding. Real-time, three-dimensional (3D) navigation software allows the neurosurgeon to localize surgical instruments and intracranial targets in 3D space. This improves localization of intracranial pathology from which more minimalist approaches may be directed.

Hardware and Configuration

Three different types of magnets can be used for MRI: permanent, resistive, and superconducting. iMRI has utilized

Graham A. Webb (ed.), Modern Magnetic Resonance, 1065–1076.
© 2008 *Springer.*

Fig. 1. Coronal (A) and lateral (B) pneumoencephalography. The lateral ventricles are visible and show no evidence of displacement.



magnets of 0.12–1.5 T, with gradient strength ranging from 12 to 33 mT/m (Table 1). Gradient strength and performance is important for rapid imaging sequence, in particular echo-planar imaging (EPI), diffusion, perfusion, and fMRI. For iMRI, inductively coupled [18] or volume coils [19] can be used. The full spectrum of imaging sequences including T_1, T_2, MR angiography, diffusion, perfusion, and fluid attenuated inversion recovery (FLAIR) have been applied to the evaluation of the utility of iMRI as an adjunct to surgery. The first iMRI system, manufactured by General Electric, consisted of a 0.5 T vertical, biplanar double doughnut magnet configuration [14]. A significant advantage of this setup is that real-time images can be acquired frequently, without interrupting surgery nor having to move the patient or the magnet. Although this initial system represented a major advance in intraoperative imaging technology, it has limitations. The system requires positioning the patient and surgeon between two magnetic poles. This results in a constrained working environment, restricted patient positioning, and the requirement for MR-compatible instrumentation. Furthermore, the magnetic field strength and gradient performance are below that needed for contemporary EPI. To partly overcome these issues, 0.2 and 0.3 T, horizontal, biplanar imaging systems were produced by Siemens and Hitachi, respectively [20,21]. For these, the surgical area is located outside of the magnetic field and the patient is moved into the magnet for image acquisition. Physically separating surgery and imaging resolved the problem of operating within a magnetic field. However, this requires interruption of surgery and moving the anesthetized, monitored patient from the surgical site to the magnet. In need of better image resolution and to maintain a patient focused environment, a movable, ceiling-mounted wide bore 1.5 T magnet was developed and manufactured by IMRIS [22–24]. With this system, conventional neurosurgical procedures are maintained and the magnet is moved to the patient for imaging (Figure 2). The higher magnetic field and improved gradient performance provides high-resolution and rapid imaging including echo planar. The system includes a versatile MR-compatible OR table accommodating various patient positioning including prone, supine, and lateral. Philips and Siemens have recently developed and installed 1.5 T iMRI systems based on stationary magnets. In the Siemens configuration, surgery takes place in the fringe field and, for imaging, the OR

Table 1: iMRI systems with main advantage and disadvantage

Manufacturer	Magnet strength	Gradient performance	Main advantage	Main disadvantage
Odin	0.12	25 mT/m	Portable	Image resolution
Siemens	0.2	20 mT/m	Unrestricted instrumentation	Image resolution
Hitachi	0.3	21 mT/m	Unrestricted instrumentation	Need to move patient for imaging
General Electric	0.5	12 mT/m	Real-time imaging	Requires MR-compatible tools
Philips	1.5	33 mT/m	Image resolution	Need to move patient for imaging
Siemens	1.5	30 mT/m	Image resolution	Need to move patient for imaging
IMRIS	1.5	20 mT/m	Image resolution	Interruption of surgery for imaging

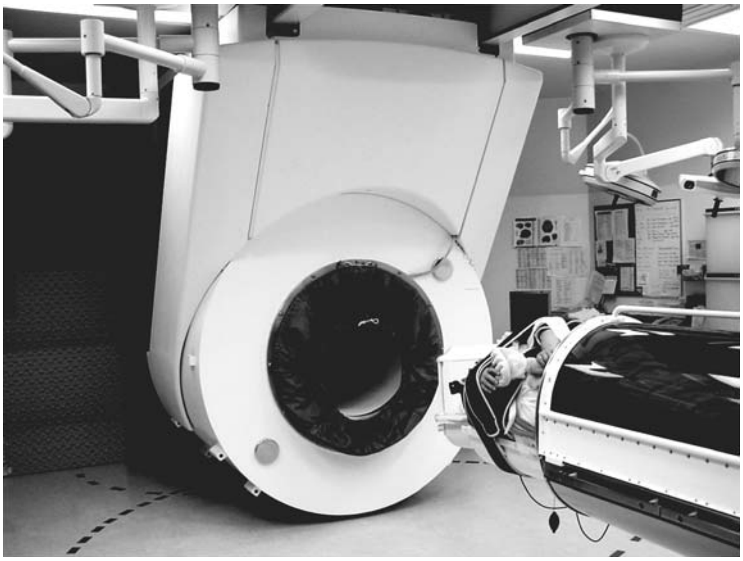


Fig. 2. Ceiling-mounted 1.5 T magnet being moved into the surgical field, together with the OR table and local RF shielding.

table is rotated to the magnet [25]. Philips designed a 1.5 T interventional/neurosurgery suite where the patient is moved by a floating tabletop from the operative table to the imaging platform for image acquisition [26]. Using the Philips system, surgeons have performed stereotaxy by reaching into the magnet, using iMRI for accurate instrument placement. To decrease the impact of iMRI in the OR environment, a small highly portable 0.12 T iMRI system, positioned under the OR table, was developed by Odin [27]. While this represented a unique innovation, imaging quality, and patient positioning are compromised by the low magnetic field and close opposition of the two magnetic poles.

Clinical Applications of iMRI

The development of iMRI has been driven by neurosurgical desire to have intraoperative imaging of CNS pathology following the induction of anesthesia and patient positioning, at various stages of the surgical dissection and as a measure of quality assurance prior to reversal of anesthesia. Despite these advantages, instrument size, weight, magnetic field, RF interference, and cost continue to pose significant challenges for widespread acceptance. Also, there has been no randomized controlled trial demonstrating superiority of iMRI-assisted neurosurgery over standard neurosurgical procedures. This in part reflects traditional education bias, the difficulty of recruiting patients for trials, crossover, and the relatively recent introduction of iMRI technology. Nevertheless, case studies and existing databases of patients who underwent iMRI procedures represent important sources of information to assess potential efficacy. Non-randomized retrospective studies matching patients based on prognostic factors are considered valuable. Examples where the use of iMRI led to modifications of the surgical procedure are also accepted as supportive evidence of utility. To fully evaluate the benefit of iMRI, randomized clinical trials, with blinded outcome assessment and long-term follow-up, are needed. At the University of Calgary, iMRI has been used to study surgery in 530 patients, 61 of which were pediatric (4 months to 18 years), with various CNS pathologies (Table 2). For each condition, surgical planning iMRI was performed after induction of anesthesia and patient positioning; interdissection iMRI was performed at various stages of the resection and quality assurance iMRI was acquired after wound closure, but before emergence from anesthesia. On average, an imaging session required 30 min. This included re-registration of surgical navigation. A total of 1930 MR studies were performed (Table 3). In 225 patients, trajectories were established by coupling surgical planning images with frameless stereotaxy (BrainLAB, Heimstetten, Germany). Time required for imaging depended on the specific MRI sequences used. Scout images (field of view 30 cm; $T_R = 35$ ms; $T_E = 15$ ms; matrix size 128×256; slice thickness 10 mm; one average) were obtained in 15 s. T_1-weighted images were obtained with spin-echo sequences (field of view 26 cm; $T_R = 400$ ms; $T_E = 12$ ms;

matrix size 192 × 256; slice thickness = 4 mm; two or three averages) in ~4 min. T_2-weighted images with fast spin-echo sequences (field of view 26 cm; $T_R = 4000$ ms; $T_E = 90$ ms; matrix size 256 × 256; slice thickness 4 mm; two averages) and FLAIR fast spin-echo sequences (field of view 26 cm; T_R, 6000 ms; T_E, 96 ms; matrix size 192 × 256; slice thickness 4 mm; two averages) were obtained in ~4 min. The following sections summarize the impact of iMRI on various neuropathologies.

Neoplasia

CNS neoplasia represented the largest group of patients ($n = 337$) undergoing iMRI-assisted neurosurgery. Similarly to other iMRI units, we have observed a case selection of patients with low-grade glioma, pituitary adenoma, and childhood tumors. This in part reflects the growing body of knowledge that outcome for these patients correlates to the extent of resection. iMRI application to tumor resection was beneficial for many reasons. Assessment of the lesion immediately prior to surgery may show progression or regression of the lesion, as compared to the diagnostic study. In some cases, this dramatically changed the planned procedure and occasionally led to the decision not to proceed, as in four of the cases (Figure 3). Surgical planning iMRI resulted in more accurate, smaller craniotomies, and narrower surgical corridors (Figure 4). Such precise operative procedures are thought to have resulted in improved outcome. Interdissection iMRI, in addition to correcting for intraoperative brain shift for frameless stereotaxy, provided an ideal method for resection control (Figure 5). This was advantageous when tumor borders were difficult to identify during microdissection, such as in many of the patients with low-grade glioma. Unsuspected residual neoplasm was observed in 9% high-grade glioma, 20% low-grade glioma, 33% pituitary adenoma, and 2% meningioma. Quality assurance iMRI, at the end of the procedure, confirmed the lack of acute surgical complications such as postoperative hemorrhage, obstructive hydrocephalus, or cerebral edema. This knowledge facilitated early postoperative care.

Spreading enhancement, particularly in patients with malignant neoplasms, was observed (Figure 6). While the nature of this phenomenon needs to be determined, it is likely to be multifactorial, reflecting disrupted blood–brain barrier, surgical manipulation, and extension of neoplasm outside borders visible with diagnostic or iMRI. This spreading enhancement was not observed in patients with meningioma, a benign encapsulated tumor, despite considerable gadolinium (Gd) tumor enhancement, and extensive surgical manipulation, including, in many cases, disruption of the arachnoid and pia. In selected cases, biopsy of the area of spreading enhancement confirmed the presence of tumor. Based on these observations, we now limit, in patients with suspected malignant neoplasms, the administration of Gd until late in the surgical dissection.

Randomized clinical trials, where patients are randomly assigned to undergo either iMRI-assisted or traditional surgery for neoplasia, are essential to assess the efficacy of iMRI over standard procedures. Patients with low-grade glioma would be ideal for such a study, as surgical resection is often incomplete and outcome may well correlate with gross resection. While the primary outcome for such a study would be the interval before tumor recurrence, other secondary outcome measures could include: accuracy of craniotomy placement, extent of tumor resection, operative complications, and length of hospital stay. A positive study would establish iMRI as *the standard of care*. Apart from surgery, iMRI can be useful to track biopsy needle and to monitor probe placement at the tumor site for brachytherapy [28], delivering viral vectors, chemotherapeutics, or heat (thermal ablation therapy) [29].

Epilepsy

The surgical management of epilepsy is based on a number of variables including the type of epilepsy, location of the epileptogenic focus, patient wishes, and expertise of the surgeon. The immediate goal of surgery is maximal safe resection of the epileptogenic tissue or

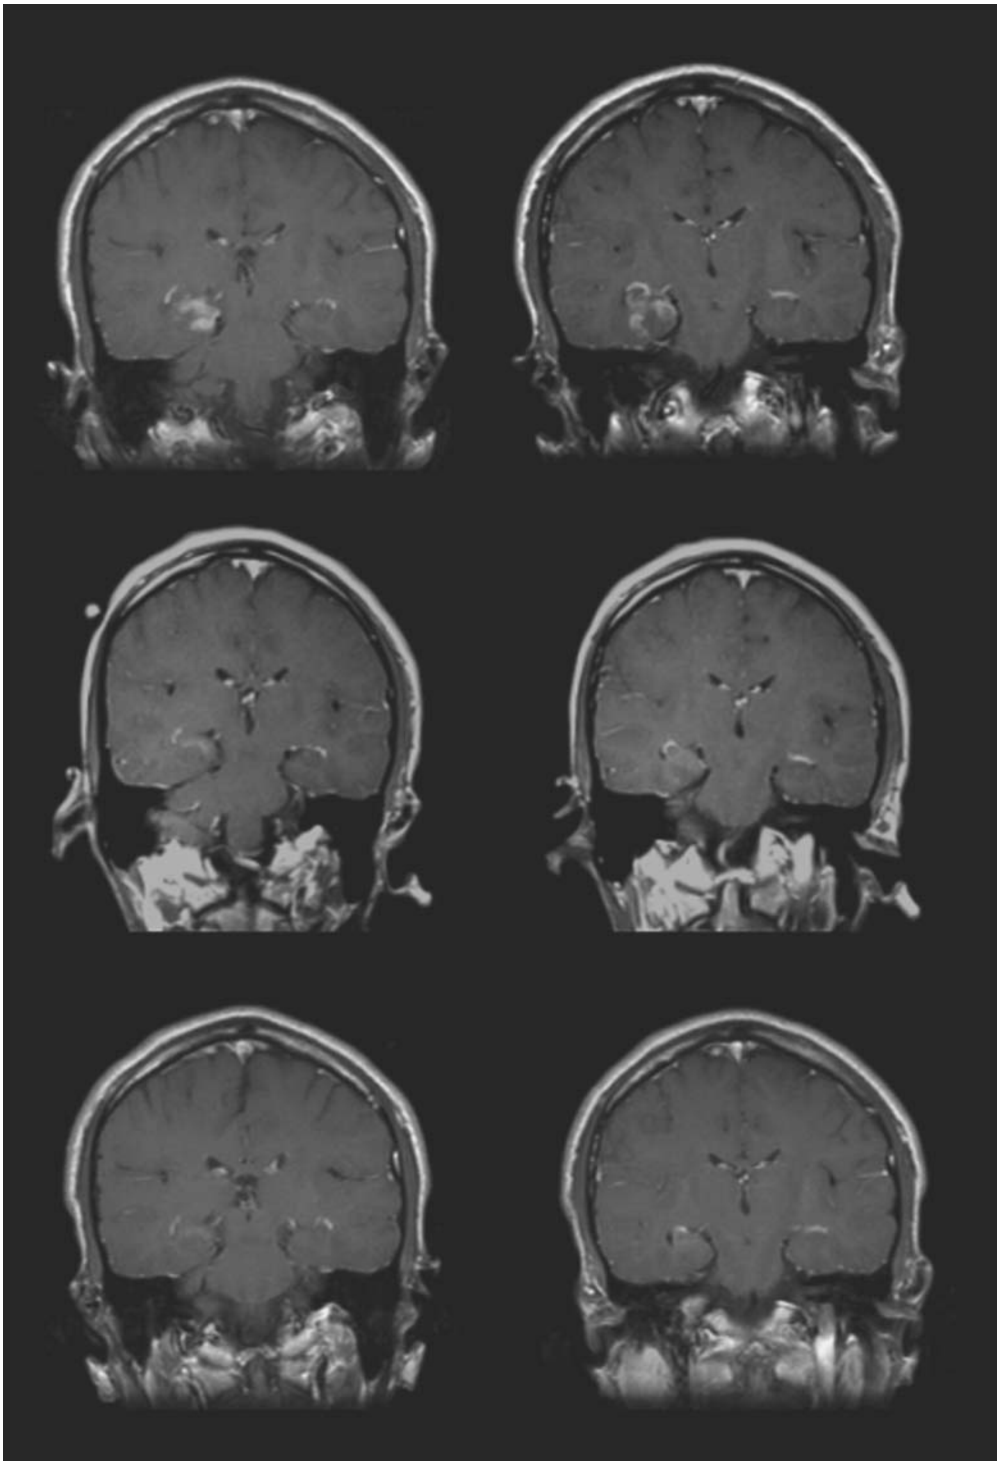

Fig. 3. T_1-Gd coronal 1.5 T MR images obtained at diagnosis (upper), surgical planning iMRI (middle) and 3-month follow-up (lower). At the time of surgical planning iMRI, the lesion had virtually disappeared and the procedure was aborted.

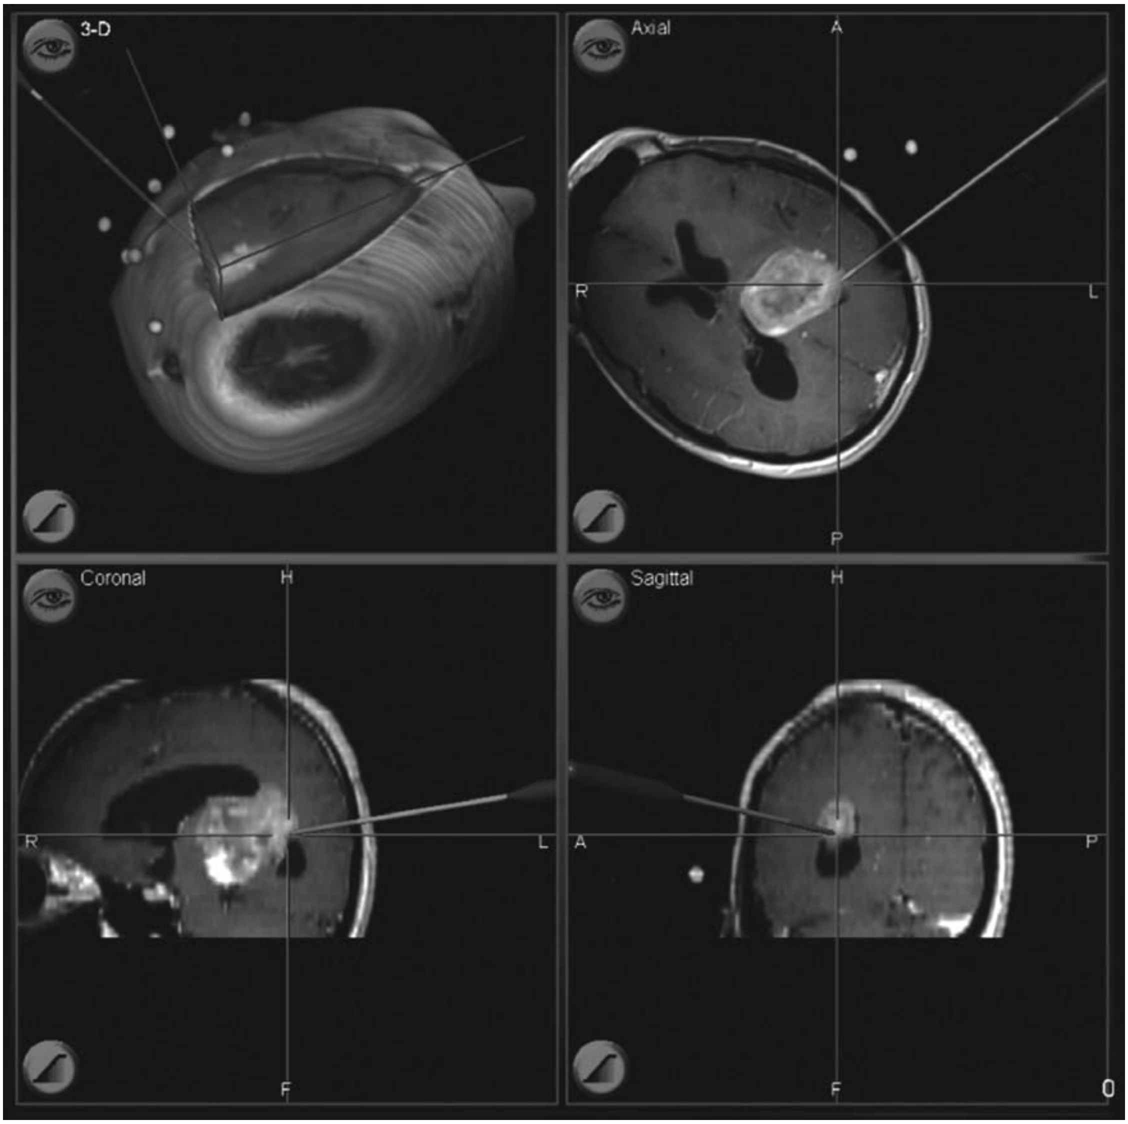

Fig. 4. Surgical planning T_1-Gd iMRI showing a large intraventricular lesion, together with registration for surgical navigation (BrainLAB, Heimstetten).

anatomical and functional disconnection, to eliminate or reduce the number of clinically significant seizures without causing major deficit. Of the 530 patients, 75 presented with intractable epilepsy. iMRI provided precise identification of abnormal tissue such as cortical dysplasia or medial temporal lobe sclerosis. When coupled to surgical navigation technology, targeting epileptogenic structures, in particular the medial temporal lobe, was optimized. As the magnet can be moved from the operative site, iMRI did not interfere with the use of surgical adjuncts such as electrocorticography, cortical mapping, and Cavitron Ultra-Sonic Aspirator (CUSA, Valleylab, Boulder, CO, USA). Selective amygdalohippocampectomy was performed in 36 of our 64 patients with temporal lobe epilepsy. We and others have found this to be as effective as temporal lobectomy for seizure control

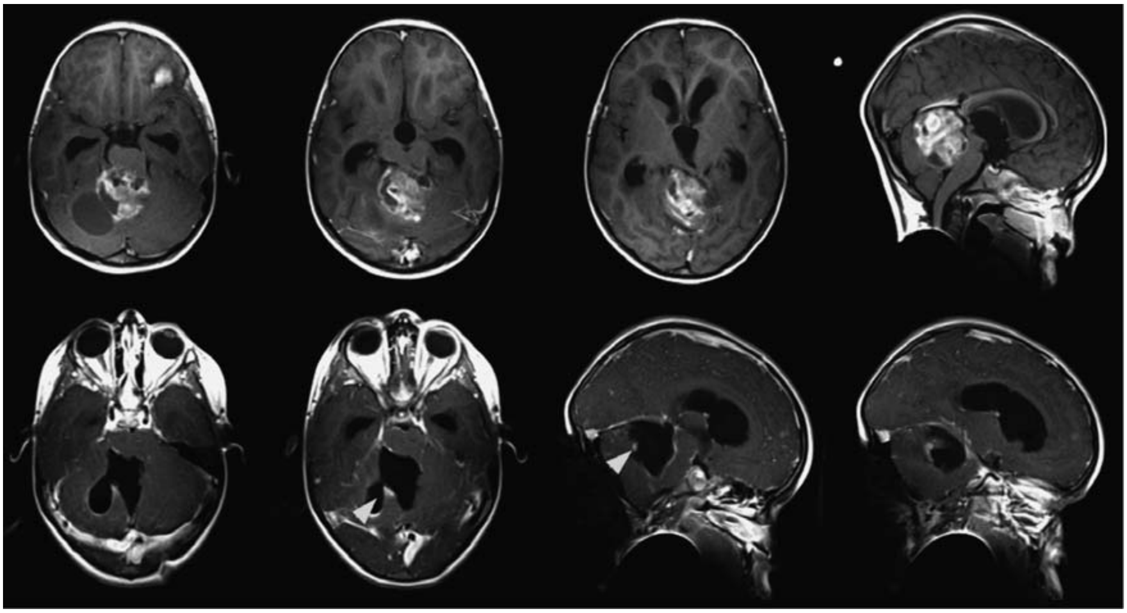

Fig. 5. Surgical planning T_1-Gd iMRI obtained from a 5-year-old boy with pilocytic astrocytoma show the large tumor with associated brain shift (upper). Interdissection images (lower) revealed unsuspected residual tumor (arrows).

[30]. Despite the fact that this procedure is routinely performed, anatomical targets can become unclear during microdissection. When approaching through the mid temporal gyrus, the amygdala may be hard to define, while with trans-sylvian dissections, it is often difficult to determine the extent of hippocampal removal. In 19% of patients with temporal lobe epilepsy, interdissection iMRI, showed unsuspected residual tissue, which was then removed (Figure 7). Notwithstanding these encouraging results, a randomized trial is necessary to both confirm the observations and determine the impact of iMRI on clinical outcome.

The assessment of cortical dysplasia requires the signal-to-noise ratio of 1.5 T or higher-field MR systems. In 4 patients with cortical dysplasia, extent of the abnormality was well assessed with the 1.5 T iMRI system, enhancing craniotomy placement and resection control.

Vascular disorders

Surgical planning iMRI significantly improved craniotomy placement for patients with arteriovenous malformation (AVM) and cavernous angioma, making lesion exposure relatively straightforward. Among the 60 patients with cerebral vascular pathology, 18 had AVM and 27 had cavernous angioma. We have, as of yet, not used diffusion/perfusion MR imaging to evaluate the effect of resecting AVM on the adjacent brain. The literature suggests that AVM resection may result in hyperperfusion of the adjacent brain. It is this consequence that is thought to contribute to the relatively high frequency (10%) of postoperative hemorrhage [31]. There were 12 patients with aneurysm and 3 had extracranial carotid occlusion. For all vascular procedures, interdissection iMRI and quality assurance iMRI confirmed complete resection of the target or treatment of the abnormality.

For patients with aneurysm, intraoperative MR angiography accurately revealed vascular anatomy and clip placement. However, clip-induced susceptibility and/or eddy current artifact interfered with evaluation of the aneurysm neck. Intraoperative assessment of the aneurysm neck will require the development of MR-invisible clips. EPI was used to identify diffusion/perfusion abnormality in the distribution of distal vascular branches, including perforators. The presence of such abnormalities would allow clip repositioning prior to irreversible brain injury (Figure 8). We have not encountered such changes and none of the aneurysm patients have suffered deficit.

Patients with carotid occlusion were symptomatic with recurrent transient ischemic attacks, and diagnostic MRI showed diffusion/perfusion mismatch. Extracranial to intracranial bypass resulted in immediate correction of the

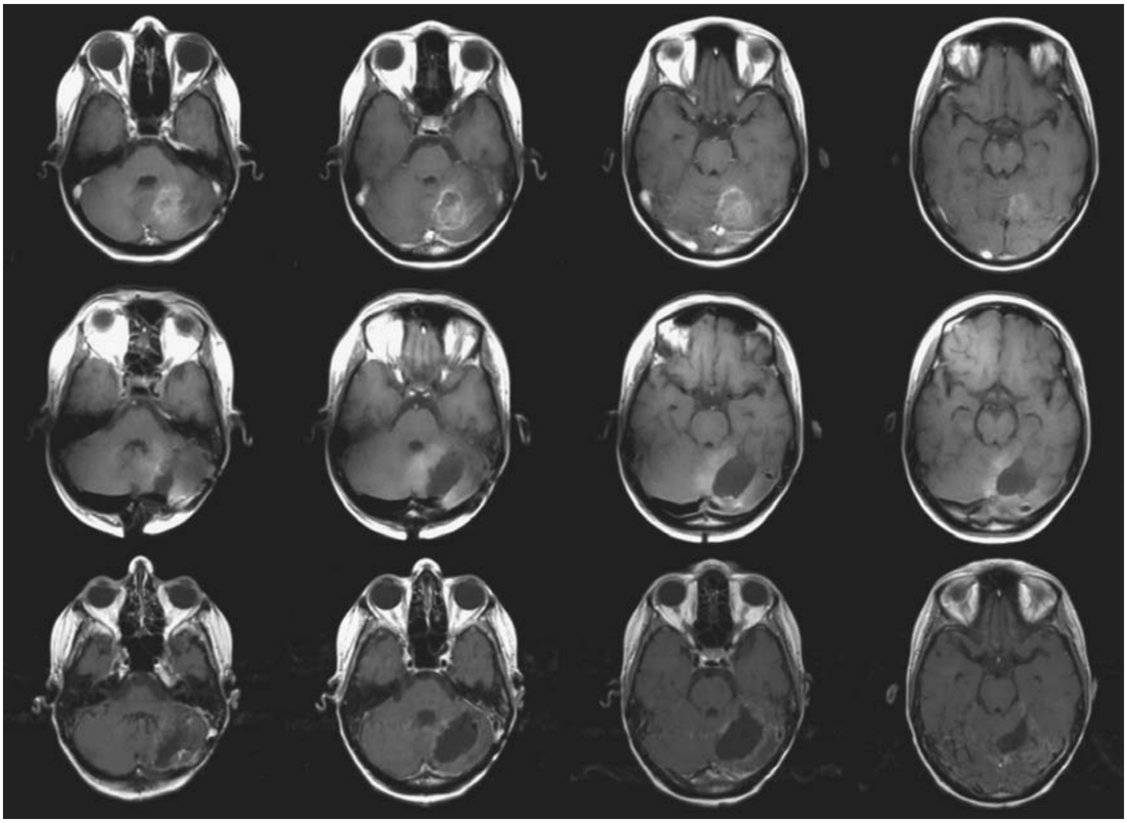

Fig. 6. Surgical planning (upper), interdissection (middle), and day 2 postoperative (lower) T_1-Gd iMRI of a patient with recurrent medulloblastoma. Diffusion of contrast well beyond the suspected tumor margin can be observed on interdissection but not on follow-up images.

perfusion deficit as shown with iMRI. Diffusion-weighted EPI quality requires a homogenous magnetic field, excellent eddy current compensation, strong gradients with fast switching times, and excellent shimming [32].

Spine

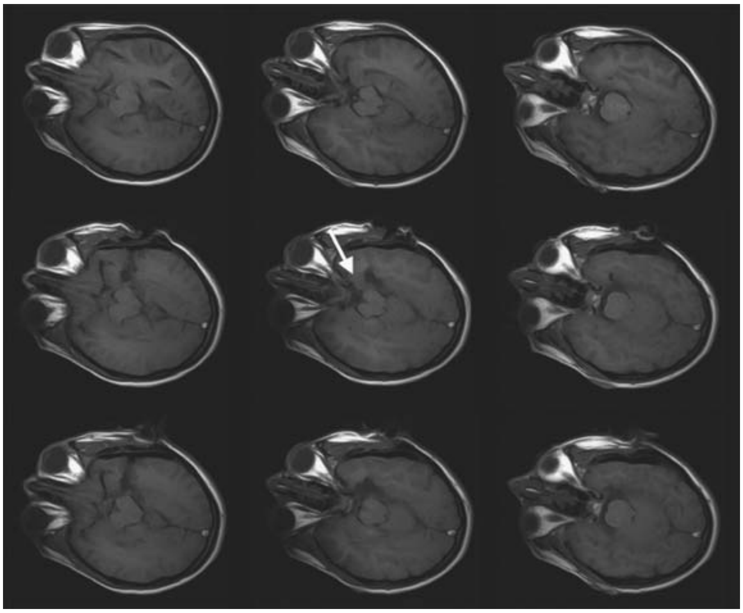
iMRI was used as an adjunct to spine surgery in 21 patients. The procedures included anterior cervical discectomy, cervical corpectomy with instrumentation, and the transoral resection of various C1/2 pathologies. iMRI with surgical navigation provided precise targeting of spinal pathology particularly lesions involving the C1/2 region, that are difficult to visualize through surgical corridors designed to limit trauma associated with extensive exposure. Interdissection images accurately determined the extent of decompression and showed the relationship of the surgical dissection to neural vascular structures (Figure 9). Extending iMRI capability to the thoracic and lumbar spine will be increasingly important as spinal surgery becomes reliant on microsurgical technique including restricted surgical corridors. The modified phased array spine RF coils are used to maximize images of the spine. The volume coil is used to transmit the RF power while the phased array coils work in the receive only mode.

Future Directions

Technology

While imaging techniques have greatly enhanced diagnostic accuracy and improved surgical outcomes, technical limitations necessitate further iMRI improvement. Increasing the magnetic field would further enhance image

Fig. 7. Surgical planning T_1-weighted iMRI from a patient with intractable temporal lobe epilepsy, showing the targeted amygdala and hippocampus (upper). Interdissection images (middle) indicate unsuspected residual amygdala (arrow). Quality assurance iMRI reveals complete dissection of the target (bottom).



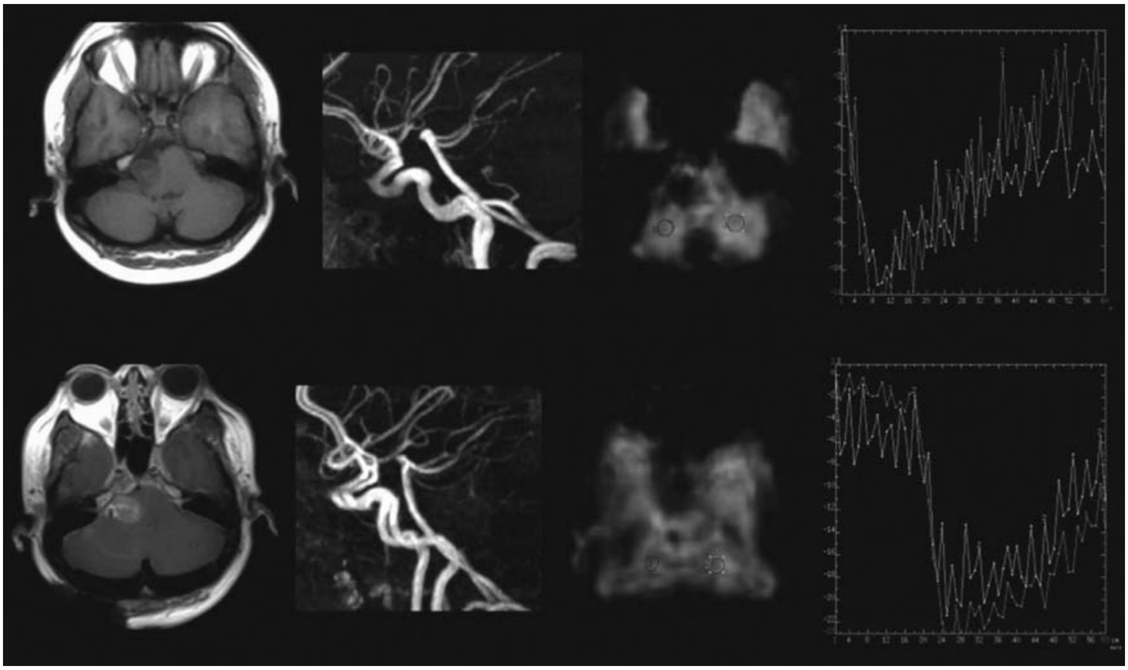


Fig. 8. Surgical planning (upper) and interdissection (lower) T_1-weighted, MR angiography, diffusion, and perfusion iMRI studies obtained from a patient with a giant left PICA aneurysm. Interdissection studies obtained 5–10 min following clip ligation of PICA show flow change within the aneurysm, parent vessel occlusion, aneurysm obliteration, and no diffusion or perfusion abnormality.

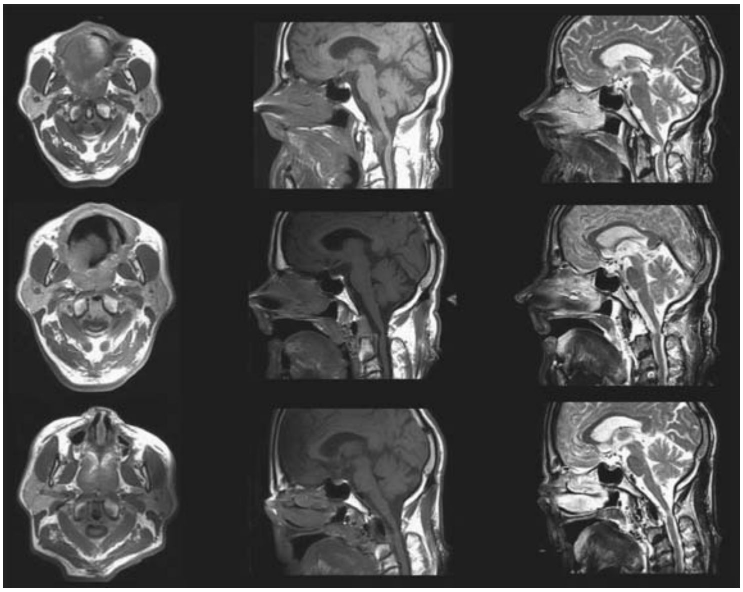

Fig. 9. T_1- and T_2-weighted iMRI from patient with retro-odontoid synovial cyst. Surgical planning iMRI (upper) show significant spinal cord compression. Interdissection iMRI show unsuspected residual spinal cord compression at the C2 level (middle). Quality assurance iMRI show optimal decompression (lower).

resolution by improved signal-to-noise ratio, although this might also lead to an amplification of susceptibility artifacts in certain areas. Improvements in RF coil design need to take advantage of improved technology while not limiting surgery. Larger RF coils, not restricting access to the operative field, would be an asset. Additional reduction in total acquisition time could be achieved by the application of phased array technology that allows the acquisition of parallel images. Enlarging the magnet bore facilitates patient positioning and the introduction of surgical technologies. To take full advantage of an iMRI system and maximize its use, the magnet should ideally be movable and sited for use in two or more rooms.

Bioinformatics

Software development has made possible 3D reconstruction of iMRI including lesion segmentation. 3D reconstruction augments lesion localization, diagnosis, and surgery planning. MRI and spectroscopic characteristics may correlate with outcome [33,34]. Multimodal fusion of MR images provides information as to the relationship of eloquent brain and vasculature to the planned surgical corridor and target.

Robotics

The introduction of iMRI has provided an imaging adjunct to surgery. Despite this and other technologies, such as microscopy, surgeons operate much like they did 100 years ago, depending to a large extent on hand–eye coordination. Robotic advances, such as tremor filtration and motion scaling permit maximal use of magnification and enable precise, tremor-free tool manipulation during surgery. Integrating robotic technology with iMRI would allow surgeons to manipulate images in real time and reduce limitations imposed by iMRI, particularly those related to a restricted working environment (GE double doughnut configuration) and disruptions in surgery related to image acquisition (1.5 T IMRIS, Siemens or Philips systems).

At the University of Calgary, we are developing an MRI-compatible, image-guided, ambidextrous robot called neuroArm [35]. Our industrial collaborator, MD Robotics (Brampton, Ontario, Canada), has successfully developed safety-critical robotic systems for the space shuttle and International Space Station. NeuroArm consists of a neurosurgical robot, main controller, and a workstation. The robot has two MR-compatible articulated arms with dextrous mechanical manipulators that grasp and move surgical tools. Each arm has 8 degrees of freedom (DOF) and are small enough to work within the 68 cm working diameter of the 1.5 T IMRIS magnet and capable of 30 μm precision (Figure 10). A 3-DOF strain gauge sensor system was integrated to provide haptic feedback to the surgeon. The workstation incorporates a computer processor, two hand controllers to manipulate the robot arms, a controller for positioning the microscope and lights, and three types of display and data recorders.

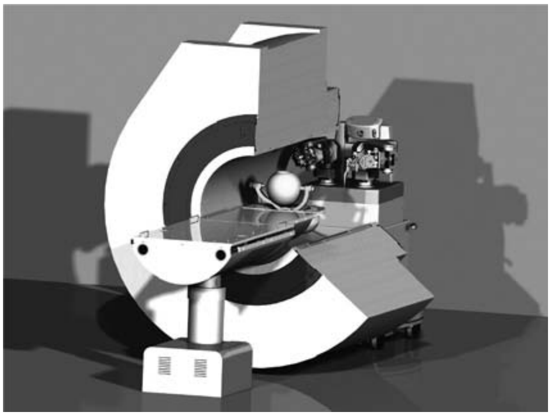

Fig. 10. NeuroArm in position for stereotaxy. The base is equipped with an extension platform (not shown), allowing the manipulator arms to reach inside the magnet bore.

The interface maximizes ergonomic comfort and minimizes surgeon fatigue.

The robotic platform and imaging environment include surgical simulation capability. This will be of increasing importance as advances in surgical technologies and associated techniques increase case complexity and produce a tyranny of choice. Risk-free rehearsal and development of patient specific interventional recipes will allow surgeons to safely take full advantage of iMRI and robotic technologies.

Acknowledgments

The authors would like to thank Boguslaw Tomanek and John Saunders for their kind suggestions. The iMRI program has been supported by a grant from the Canadian Foundation for Innovation. The iMRI system is being marketed by IMRIS (info@IMRIS.com).

In Vivo Magnetic Resonance Spectroscopy in Breast Cancer

Uma Sharma and N.R. Jagannathan
Department of NMR, All India Institute of Medical Sciences, New Delhi 110029, India

Abbreviations: MR, magnetic resonance; MRI, magnetic resonance imaging; MRS, magnetic resonance spectroscopy; ^{1}H MRS, proton magnetic resonance spectroscopy; ^{31}P MRS, phosphorus magnetic resonance spectroscopy; CE-MRI, contrast-enhanced magnetic resonance imaging; VOI, volume of interest; CSI, chemical shift imaging; MRSI, magnetic resonance spectroscopic imaging; STEAM, stimulated echo acquisition mode; PRESS, point resolved spectroscopy; CHESS, chemical shift selective; W–F, water-to-fat ratio; PME, phosphomonoester; PDE, phosphodiester; PCr, phosphocreatine; SV, single-voxel.

Introduction

Breast cancer is the most common cancer affecting women and is a significant health care problem, worldwide [1–3]. Breast cancer is classified as either ductal or lobular, depending on its morphological origin and similarities to the normal cellular components. Considerable heterogeneity among breast tumors demands highly accurate diagnostic techniques. Methods like X-ray mammography, ultrasound, and physical examination are often limited in sensitivity and specificity, especially in young women [4–6]. Magnetic resonance (MR) mammography and contrast-enhanced magnetic resonance imaging (CE-MRI) methodologies have greatly improved the ability to differentiate malignant from benign breast tumors [7–11] (see chapter by Kaiser). However, the reported specificity of the above studies is widely variable [8] and does not provide any metabolic information.

Recently, there has been an increasing interest in augmenting breast MRI with magnetic resonance spectroscopy (MRS) investigations by using the biochemical information to increase the specificity in differentiating benign from malignant tumors. Results of *in vivo* proton (^{1}H) [12–25] and phosphorus (^{31}P) [26–28] MRS, *ex vivo* and *in vitro* [29–32], and cell line [33,34] studies reported to date suggest that malignant breast tumors exhibit elevated levels of choline-containing compounds (total choline, TCho). In the case of MRS applied to fine needle aspiration biopsies (FNAB), the creatine to choline ratio can provide the pathological diagnosis with accuracies in the late 90th percentile [32,35]. This chapter reviews the potential of *in vivo* MRS (both ^{1}H and ^{31}P) in breast cancer especially in relation to the various methodological issues involved, technical limitations, diagnostic specificity, clinical applications, and future directions.

In vivo Localization in MRS

The basic requirement of *in vivo* localized MRS is to acquire the signal from a particular volume of interest (VOI) with optimal sensitivity. In the last 20 years, the availability of gradients has led to the development of localization techniques to obtain spectra from specific VOI. Magnetic field gradients in either the B_0 field as in imaging or the B_1 (radio frequency) field are used for localization of a particular volume. *In vivo* MRS began with the analysis of isolated tissues and surface regions. Most ^{31}P studies on breast cancer use surface coils, which are one of the earliest methods of localization. Surface coils provide rough localization. However, spatial selectivity can be achieved by varying the radio frequency pulse length. The disadvantages include extremely inhomogeneous transverse magnetic field, difficulty in assessing VOI that is below the surface, and contamination of signals from extraneous tissues. For these reasons, surface coils are used with other techniques like depth resolved spectroscopy, DRESS [36], which uses B_0 magnetic field gradients and a frequency selective pulse for localization. Depth resolved spectroscopy is also possible by using B_1 changes [37].

Currently employed image guided localization methods use proton images acquired in three orthogonal planes (transverse, sagittal, and coronal) to guide the placement of VOI. The magnetic field gradients spatially encode the resonance frequencies and the frequency selective pulse excites the spin distribution within the sample. Position, size of VOI, and the actual shape depend on the slice profile of the selective pulses. Localization methods acquire spectra either as single-voxel (SV) or as multivoxel [chemical shift imaging (CSI) or magnetic resonance spectroscopic imaging (MRSI)]. MRSI offers many advantages over SV techniques, such as localized spectra from many locations and small VOIs can be acquired simultaneously which can be used to obtain the metabolite

Graham A. Webb (ed.), Modern Magnetic Resonance, 1077–1086.
© 2008 *Springer.*

images. The pixel intensity in these images is proportional to the relative concentrations of the metabolites which is useful in visually assessing the spatial variation in the metabolite concentrations. However, the technique suffers from some disadvantages, such as signal from a voxel is prone to contamination from outside the VOI. This contamination occurs due to discrete and finite sampling, since the number of phase-encoding steps is typically more limited than normal imaging acquisitions. In addition, shimming the magnetic field over large volume especially in breast due to heterogeneity of tissues and long acquisition times are other disadvantages. In recent times, echo-planar imaging-based MRSI sequences which offer less image acquisition times have also become available. The most commonly used pulse sequences in breast cancer MRS are image selected *in vivo* spectroscopy (ISIS) [38], stimulated echo acquisition mode (STEAM) [39,40], point resolved spectroscopy (PRESS) [41], and CSI or MRSI [42,43]. In breast ^{1}H MRS, detection of resonances from metabolites with lower concentration in the presence of a large water and lipid signals is a major problem. Chemical shift selective (CHESS) radio frequency pulses that excite a limited narrow band (~60 Hz) of frequencies corresponding to the water signal are used to suppress the water signal [44]. Sequences that simultaneously suppress both water and lipid resonances are also being developed (*vide infra*).

^{31}P MR Spectroscopy

^{31}P MR spectra provide information on cellular metabolism by measuring various phosphorus metabolites and have been reviewed recently [26,27]. Most studies were carried out at 1.5 T with the patient positioned either supine or prone with a dual ^{1}H/^{31}P surface coil covering the area of the tumor. Shimming is carried out at ^{1}H frequency. The measurement methodology adopted by different groups varies in relation to the use of repetition time, size of coil used, and other experimental parameters. Figure 1A shows the ^{31}P MR spectrum obtained from a normal volunteer, and reflects the level of various

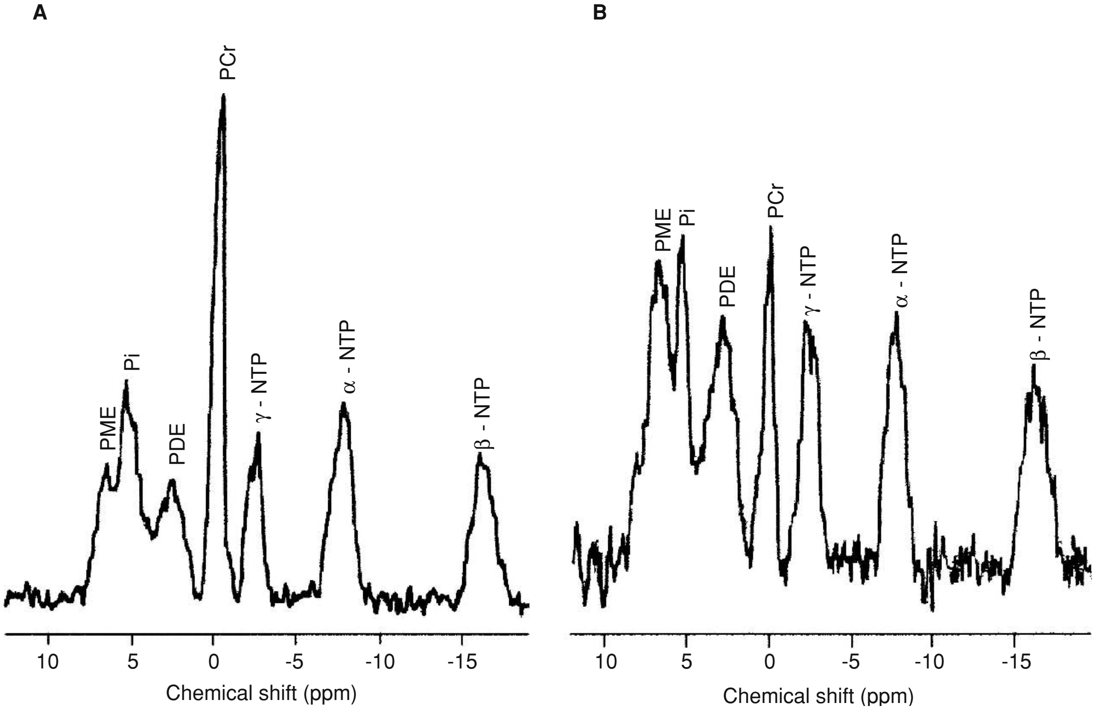

Fig. 1. (A) ^{31}P MR spectrum from normal breast tissue of a volunteer. Peak assignment corresponds to adenosine triphosphate (ATP), phosphodiesters (PDE), phosphomonoesters (PME), phosphocreatine (PCr), and inorganic phosphate (Pi). (B) ^{31}P MR spectrum from a patient suffering from infiltrating duct carcinoma of the breast. Spectra were obtained using a 10 cm surface coil with a single RF pulse.

phosphorus containing metabolites. In general, considerable variations in the ^{31}P metabolite profile of the normal breast were observed during the menstrual cycle [45,46]. Pre-menopausal women showed a rise in phosphomonoester (PME) signal at the late follicular stage of the menstrual cycle and less signal at the early luteal phase [46]. Phosphodiester (PDE) was maximal at the early follicular phase, and minimal at the late follicular stage. Twelves *et al.* [45] have reported lower PME and a high PDE/PME ratios during the second week of menstrual cycle. It is also reported that PME is increased in lactating breast compared with non-lactating post-menopausal women [45,47]. In general, ^{31}P MR signals are lower in post-menopausal women compared with pre-menopausal women [45,46].

Figure 1B shows the ^{31}P MR spectrum of a patient suffering from infiltrating duct carcinoma with elevated levels of PME and PDE, similar to that reported by other researchers [26,28,48–51]. In general, breast tumors have higher total phosphate content compared to the normal breast tissues of non-menstruating women [26,48]. The potential of ^{31}P MRS in distinguishing benign lesions from malignant has also been reported on the basis of elevated PME [49,50]. Biopsy results demonstrate that carcinomas contain three times more adenosione triphosphate and PME than benign breast lesions [29]. Recently, the utility of *in vivo* ^{31}P MRS for patients with various malignant and benign diseases has been evaluated [28]. Significant differences in PME and the ratio of PDE to phosphocreatine in malignant tumors were observed compared to normal breast tissue. However, no difference was observed between malignant and benign tumors suggesting that ^{31}P MRS is not helpful in differential diagnosis between benign and malignant lesions [28]. The use of ^{31}P MRS to monitor the response of breast tumors to chemotherapy has also been reviewed [26]. Serial measurements of localized ^{31}P MRS of breast cancer patients using the image guided *in vivo* spectroscopy sequence [26] was carried out both before and after chemotherapy showing decreased PME that was found to be associated with the response of the disease, while an increase in PME was associated with the disease progression [12,45,51–53].

Even though ^{31}P MRS studies were promising, they gave diverse results [28]. Moreover, its use in characterizing the tumors *in vivo* is hampered by lower MR sensitivity for detecting ^{31}P signals (sensitivity 1/10 of ^{1}H MRS). To achieve a similar signal-to-noise ratio of metabolites detected by ^{1}H MRS, a ^{31}P MRS study requires a voxel that is about 10 times larger than that used in ^{1}H MRS and hence can be performed only on large sized tumors. In addition, ^{31}P MRS requires special hardware that may not be available with all clinical scanners. By contrast, ^{1}H MRS examination can easily be integrated into a routine MRI examination. In view of this, considerable interest has been shown in recent years in evaluating the role of *in vivo* ^{1}H MRS in breast cancer.

^{1}H MR Spectroscopy of Breast

Presently seven groups are involved in breast *in vivo* ^{1}H MRS [12–25]. Katz-Brull *et al.* [54] have reviewed these reports and carried out pooled analysis of the existing ^{1}H MRS data. However, several methodological issues need to be addressed and these are outlined below.

Methodological Issues Related to Proton *in vivo* Breast MRS

Most *in vivo* ^{1}H MRS of human breast cancer studies reported to date were performed at 1.5 T except for the work of two groups [24,55,56]. The patient is usually positioned prone and this has some technical advantages, in that a tumor may be relatively distant from other structures that provide a substantial signal, such as chest wall muscle. However, positioning a surface coil is difficult in prone position and thus, a relatively large volume coil is often employed which has the disadvantage of potentially reducing the signal-to-noise ratio. In the supine position, a surface coil can be used, but contamination from chest wall and motion artifacts may increase. An additional disadvantage is the loss of signal from lesions that are not close to the surface coil of the breast.

A dedicated single or bilateral surface receive coil (custom/commercial make) is used for optimal signal reception with the body coil as transmitter. Automatic tuning and electronic decoupling is used for optimal signal reception. Some groups have used a transmit–receive breast coil (usually custom made) for their study [15,23,24]. Patients are positioned prone with the breast fitting into the cup of the coil. Followed by localizer images, T_1-weighted images in sagittal plane are obtained using a spin-echo sequence. To identify precisely the full extent of the irregular, speculated border of malignant tumors, lipid saturated proton MR images in the transverse, and coronal planes are acquired. Some centers use CE-MRI to localize the tumor region. Kvistad *et al.* used non-contrast MRI, when the tumor was easy to localize, otherwise CE-MRI was used for positioning the voxel [16]. Caution should be exercised when MRS is performed after using contrast agents to identify the tumor, since gadolinium has been reported to influence the *in vivo* detection of TCho [57]. Depending on the tumor size, voxels of appropriate dimension are chosen and positioned well within the tumor area.

Magnetic field shimming must be carried out both globally and over the voxel region to optimize the field homogeneity and for good water-suppression. In our experience, the line width after voxel shimming typically should correspond to 10–25 Hz for the lipid peak in case of normal breast tissue and 5–20 Hz for the water peak in patients with breast tumors. If this is not achieved, the quality of water-suppression will be poor leading to broad or no detectable choline signal. Solvent suppression pulses can be optimized to have narrow bandwidth excitation to minimize spectral perturbations outside the desired area. Water-suppressed and un-suppressed localized spectra with an adequate number of scans are acquired using an appropriate echo time (TE = 30/135/270/350 ms). Chemical shifts are reported using water as the internal standard at 4.7 ppm. The total study time per patient ranges between 60 and 75 min including MRI and MRS. Table 1 summarizes details of the pulse sequence, acquisition parameters, etc. used in various studies reported in the literature.

Table 1: Summary of experimental details used in various ^{1}H MRS studies

Study and reference	Patients, number of cases studied, and other details	Sequence used and SV/MRSI	Water or lipid suppression sequence used	Field, coil used, methods, acquisition parameters, sensitivity, and specificity
Roebuck *et al.* [13]	Malignant, $n = 10$ (pre-therapy); benign, $n = 7$	STEAM; SV	Water; CHESS	1.5 T; single breast multicoil receive; CE-MRI; TR = 2 s; TE = 31, 270 ms; voxel size = 0.7–9.8 ml; sensitivity = 70%; specificity = 86%
Jagannathan *et al.* [14,17]	Malignant, $n = 17$ (pre-therapy); $n = 34$ (post-therapy); benign, $n = 2$; controls, $n = 14$	STEAM; SV	Water; CHESS	1.5 T; bilateral surface receive coil; non-CE-MRI; TR = 3 s; TE = 135 ms; voxel size = 1–8 ml
Kvistad *et al.* [16]	Malignant , $n = 11$ (pre-therapy); $n = 1$ (post-therapy); benign, $n = 11$; control, $n = 11$; lactating, $n = 7$	PRESS; SV	Water frequency selective inversion	1.5 T; single breast receive coil; non-CE and CE-MRI; TR = 2 s; TE = 135, 350, 450 ms; voxel size = 1–25.2 ml; sensitivity = 82%; specificity = 82%
Jagannathan *et al.* [22]	Malignant, $n = 46$ (pre-therapy); $n = 35$ (post-therapy); benign, $n = 14$; control, $n = 16$; lactating, $n = 1$	STEAM; SV	Water; CHESS	1.5 T; bilateral surface receive coil; non-CE-MRI; TR = 3 s; TE = 135 ms; voxel size = 1–27 ml; sensitivity = 78%; specificity = 86%
Cecil *et al.* [18]	Malignant, $n = 23$ (pre-therapy); benign, $n = 15$	STEAM; SV	Water; CHESS	1.5 T; phased array multicoil receive; non-CE and CE-MRI; TR = 2 s; TE = 31, 270 ms; voxel size = 1–3.4 ml; sensitivity = 83%; specificity = 87%
Yeung *et al.* [19]	Malignant, $n = 24$ (pre-therapy); benign, $n = 6$	PRESS; SV	Water frequency selective inversion recovery	1.5 T; double breast receive coil; CE-MRI; TR = 2 s; TE = 38, 135, 270 ms; voxel size = 1–95 ml; sensitivity = 92%; specificity = 83%
Gribbestad *et al.* [15]	Malignant, $n = 12$ (pre-therapy); control, $n = 10$	PRESS; SV	Water frequency selective inversion	1.5 T; double breast transmit-receive coil; non-CE-MRI; TR = 2 s; TE = 136 ms; voxel size = 8–27 ml
Gribbestad *et al.* [61]	Malignant, $n = 6$ (pre-therapy)	PRESS; SV	Water and lipid using MEGA	1.5 T; standard coil; CE-MRI; TR = 1.6 s; TE = 270 ms; voxel size = 3.4 ml
Stanwell *et al.* [23]	Malignant, $n = 21$ (pre-therapy); control, $n = 43$; lactating , $n = 3$	PRESS; SV	VSS and CHESS	1.5 T; single breast transmit–receive coil; non-CE-MRI; TR = 2 s; TE = 135, 350 ms; voxel size = 3.4 ml

Table 1: (*Continued*)

Study and reference	Patients, number of cases studied, and other details	Sequence used and SV/MRSI	Water or lipid suppression sequence used	Field, coil used, methods, acquisition parameters, sensitivity, and specificity
Bolan *et al.* [24]	Malignant, $n = 86$ (pre-therapy); $n = 14$ (post-therapy); control, $n = 5$	LASER; SV	VAPOR	4 T; single breast transmit–receive coil; CE-MRI; TR= 3 s; TE = 45–196 ms; voxel size = 0.4–6 ml
Thomas *et al.* [66]	Malignant, $n = 8$; control, $n = 9$	2D, SV CABINET	No suppression	1.5 T; phased array coil; TR = 2 s; TE = 30 ms; voxel size = 1 ml
Jacobs *et al.* [25]	Malignant, $n = 8$ (pre-therapy); benign, $n = 7$	PRESS; MRSI	Water and lipid; CHESS and STIR	1.5 T; phased array coil; TR = 2 s; TE = 272 ms; voxel size = 1 ml
Meisamy *et al.* [56]	Malignant, $n = 16$; MRS both pre- and post-therapy	SV, localization with adiabatic selective refocusing	VAPOR	4 T; single breast quadrature transmit–receive coil; TR = 3 s; TE = 45–196 ms; voxel size = variable dimensions according to tumor size

Note: TR = time for repetition; TE = time for echo; LASER = localization by adiabatic selective refocusing; STIR = short inversion time recovery; VAPOR = variable pulse power and optimized relaxation; CABINET = coherence transfer based spin-echo spectroscopy; MEGA = MEscher GArwood (named after the authors); VSS = very selective suppression.

In our work, the observation of TCho was based on strict experimental criteria [22], namely: (i) the line width of the un-suppressed water peak to be around 5–20 Hz and (ii) the ratio of the water-suppression factor ≥ 20. If these criteria were not met, the data were discarded [22]. It is our experience that these criteria are essential since the observation of choline may be affected by poor shimming, the relative position of the voxel in relation to the surface coil, coil loading, and partial volume effects [22,24,54]. Moreover, SV-MRS of breast is sensitive to the size and placement of the voxel because of the heterogeneous distribution of TCho in the breast [24].

In addition, quantification of metabolite levels in breast is more difficult because of the heterogeneous distribution of the glandular and adipose tissues. Absolute concentration of TCho in breast lesions has also been reported using a phantom containing 1 mmol/l solution of choline placed in the multicoil array [13]. Recently, Bolan *et al.* used water as an internal reference peak for quantification of TCho [24]. This approach compensates for the partial volume of adipose tissue in the voxel and leads to a molal (mol/kg) concentration of water-soluble metabolites. Use of an appropriate echo time in breast *in vivo* spectroscopy involves a trade-off between signal intensity (high with short echo time) and signal contrast (the ability to resolve the composite choline signal from the lipid signal, which is higher with long echo time). The use of long echo times (≥ 135 ms) is preferred, despite the loss of signal intensity, for improved visibility of TCho signal because of a decreased overlap with the lipids [13,19,22]. Recently, Stanwell *et al.* have demonstrated the importance of referencing and optimized post-acquisitional data processing to improve the spectral resolution of MR spectra [23]. This allows the resolution of the composite choline resonance into its constituent components and helps in improving the specificity of *in vivo* MRS method [23]. In addition, water-to-fat (W–F) (lipid) ratio can also be calculated using the respective peak areas (using area under the water and the major lipid peak) from the un-suppressed MR spectra [12,14,17].

Interpretation of ^{1}H and ^{31}P spectra should include the age and the menopausal status of the patient. Postmenopausal women have more adipose tissue compared to glandular tissue. In pre-menopausal women, glandular tissue can give an adequate signal, and this needs to be considered both in the measurement strategies as well as in interpreting the spectra obtained. In a study by Stanwell *et al.* composite choline signal was observed in three non-lactating normal volunteers [23]. The chemical shift of this resonance was found to differ from that recorded from patients with malignant disease. When ^{1}H MRS on two of these volunteers was repeated once a week for a period of 8 weeks [23], in one volunteer the choline resonance was absent at different stages throughout the menstrual cycle but re-appeared in the next cycle. In the other volunteer, the resonance was always detectable but appeared to fluctuate during the 8-week period. However, long-term follow-up of these individuals has revealed no disease.

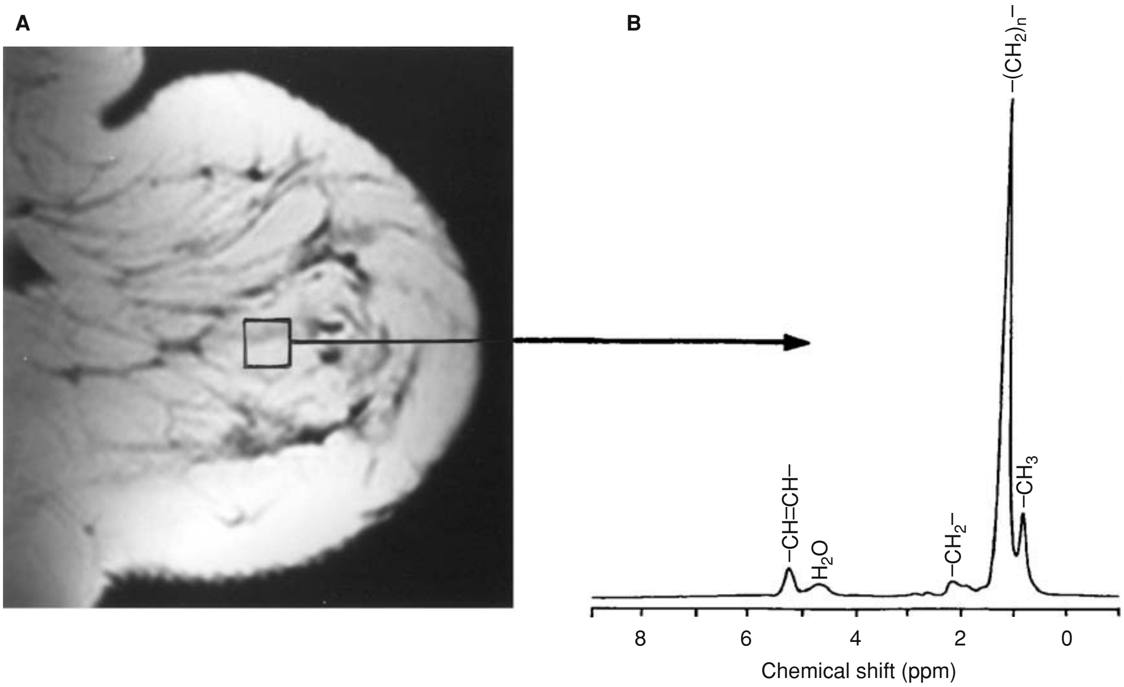

Fig. 2. (A) T_1-weighted axial image from a volunteer using spin-echo sequence with the following parameters: TR = 600 ms, TE = 15 ms, and slice thickness = 4 mm. (B) ^{1}H MR spectrum acquired from an 8 ml voxel localized in the normal breast tissue at TE = 135 ms using PRESS sequence.

Comparison of ^{1}H MRS of Normal and Malignant Breast Tissues

Water-to-Fat Ratio

A typical ^{1}H MR spectrum obtained from our laboratory using STEAM sequence (without water-suppression) from the normal breast tissue of a volunteer is shown in Figure 2B while the corresponding voxel location in Figure 2A. Lipid resonance dominates and the assignment of the various lipid resonance peaks are as shown. A ^{1}H spectrum without water-suppression from the tumor of a patient suffering from infiltrating duct carcinoma is shown in Figure 3B and the voxel location in Figure 3A. In tumor spectrum, the water peak dominates with low contributions from protons of the fatty acid chains in comparison to the normal breast tissue of controls and from the unaffected contralateral breast of the patient. Elevated W–F ratio characterizes the breast tumor. Similar findings have been documented by several others [12,14,17]. Observation of elevated W–F ratio in breast cancer patients is in agreement with the generally established trend that tumors have considerably higher water content [12,58,59]. Mackinnon *et al.* [60] reported changes in lipid content with tumor development and progression. In patients receiving chemotherapy, resulting in the reduction of primary tumor size, the W–F ratio showed a statistically significant ($p < 0.01$) decrease compared with the pretherapy value, thus providing a non-invasive indicator of favorable clinical outcome of chemotherapy [14,17]. The method thus provides the potential for non-invasively monitoring and assessing the response of breast cancer to chemotherapy. However, due to overlap of W–F values between benign and malignant lesions it has limited utility [59] and hence a search for other biochemical/s, which can be used as marker for malignancy, was undertaken.

Choline Signal

Water-suppressed ^{1}H MR spectra of breast tumor showed, in addition to the residual water and lipid peak, a peak at 3.2 ppm due to TCho as shown in Figure 3C. In general, the observation of TCho from breast tumors is hampered by the presence of huge water and lipid signals. However, if the strict experimental criteria outlined earlier are followed, then the observation of TCho is feasible. Evaluation of a pulse sequence to suppress simultaneously both the water and lipid signals to improve the detection

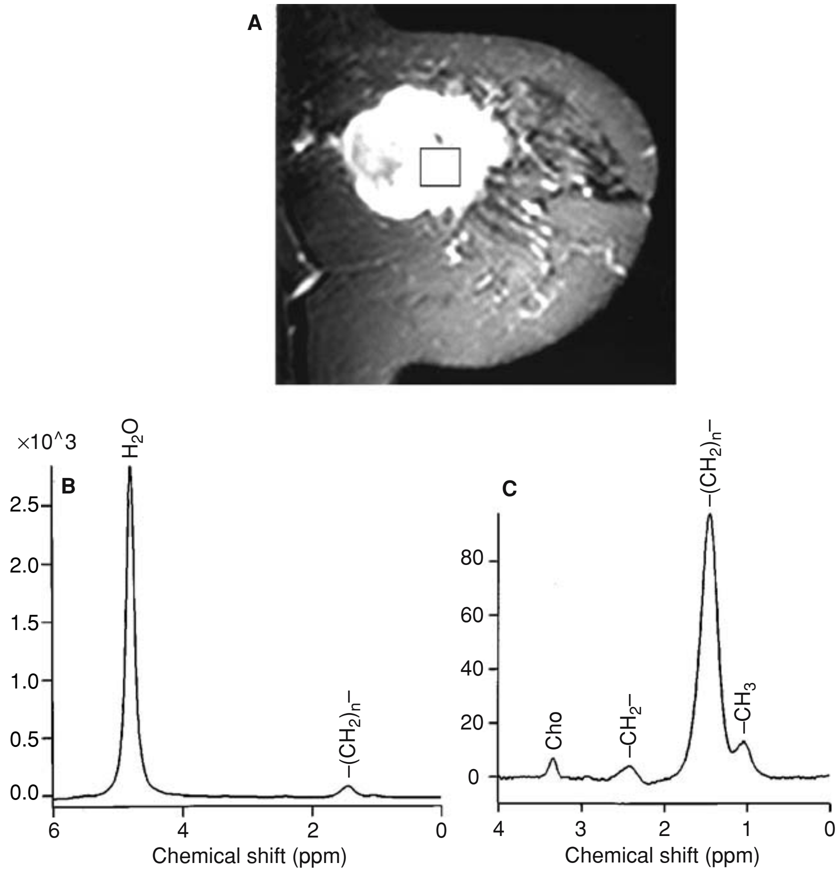

Fig. 3. (A) T_2-weighted lipid-suppressed sagittal MR image of a patient suffering from infiltrating duct carcinoma of the right breast, the tumor is seen as hyper-intense area. ^{1}H MR spectrum from an 8 ml voxel positioned in the tumor of the same patient obtained at TE = 135 ms using PRESS sequence: (B) without water-suppression and (C) with water-suppression.

of choline resonance is currently underway in our laboratory (see Figure 4). Lipid/water signal reduction is obtained using the spectral saturation method, by which transverse magnetization is dephased selectively before and after the second slice selective 180° spin-echo pulse. This dephasing is defined to affect both the water and lipid signals from 0.7 to 2 ppm, following the procedure of Mescher *et al.* [61]. Recently, Gribbestad *et al.* have also used a similar sequence to suppress the signals from water and lipid [62].

Of the various TCho (Cho, glycerophosphocholine, and phosphocholine) that contribute to the *in vivo* peak at 3.2 ppm, an increase in phosphocholine has been documented [23,33,63]. Elevation of TCho levels in malignant breast tumors compared to benign cases from *in vitro* MRS of FNAB and tissue has also been reported [30,31,32]. Results of ^{1}H *in vivo* breast MRS investigations to date have shown that the TCho resonance is specific to malignant tissue and can be used to differentiate cancerous from benign tissue. Combined analysis of the published reports reveal that the overall sensitivity and specificity of MRS is 83 and 85%, respectively [54]. The details are as presented in Table 1. In younger women, differentiation of benign from malignant lesion is important since the incidence of benign breast disease in young women is high [64,65] and mammography examination has lower sensitivity. Results from Cecil *et al.* [18], Yeung *et al.* [19], and Roebuck *et al.* [13] show that in younger patients ($\leq$40 years of age), ^{1}H MRS has a sensitivity of 100% and a specificity of 89–100% in detecting malignancy.

Several factors that limit the sensitivity of ^{1}H MRS were discussed earlier and the false negative results reported in many studies are ascribed mainly to technical limitations. For example, if the tumor size is small,

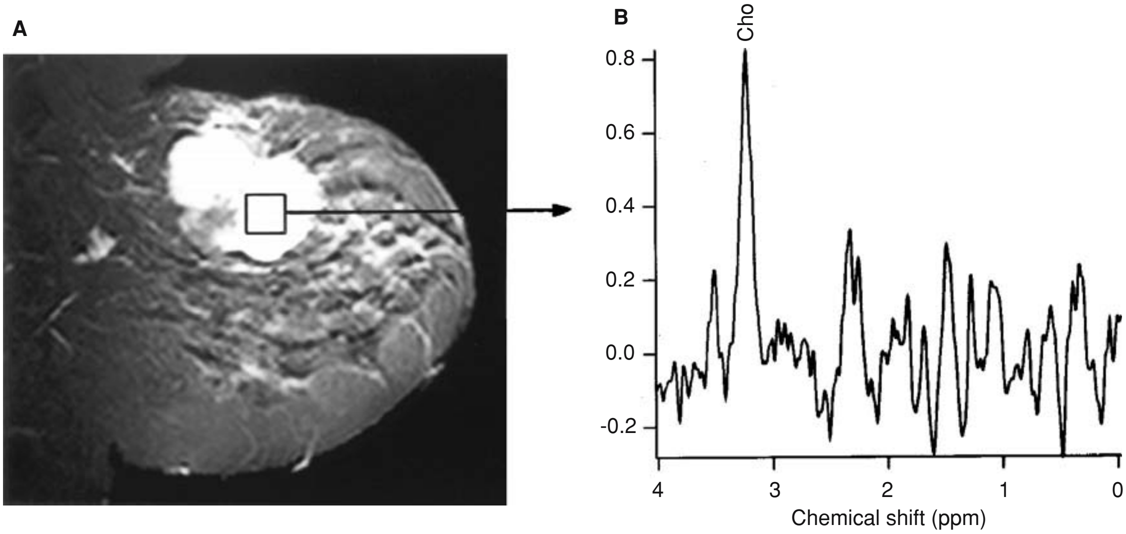

Fig. 4. (A) T_2-weighted lipid-suppressed sagittal MR image of a patient suffering from infiltrating duct carcinoma. (B) ^{1}H MR spectrum from an 8 ml voxel positioned in the tumor of the same patient obtained at TE = 270 ms using PRESS sequence with both the water and the lipid peak simultaneously suppressed.

relatively long acquisition time is required resulting in the patient becoming restless leading to movement artifacts. This also could lead to incorrect sampling of the tumor, thereby leading to contributions from surrounding fatty tissue. Moreover, movement of a patient would also lead to incorrect sampling and hence to false diagnosis. Incorrect sampling may also play a role in the detection of the choline signal. Few benign cases also showed TCho signal [16,18,19,22]. Detection of choline from the normal breast tissue of lactating women has also been reported [16,22,23]. This observation implies that the interpretation of spectra from such patients needs to be evaluated with caution and also points out the limitation of using TCho as a marker of malignancy. Stanwell *et al.* have documented that the main contribution to the TCho resonance observed in lactating breast is from the glycerophosphocholine [23]. They have documented that optimized post-processing of the spectra resolved a resonance at 3.22 ppm, consistent with phosphocholine, in patients with cancer. In contrast, the spectra recorded for three false positive volunteers and the three lactating mothers had a resonance centered at 3.28 ppm (possibly taurine, *myo*-inositol, or glycerophosphocholine).

Recently Jacobs *et al.* [25] have reported on a proton MRSI of breast cancer patients; their results show that TCho from malignant tissue was significantly elevated compared to benign breast tissue. The potential advantages of MRSI over SV-MRS include the ability to assess multiple lesions and tissues with normal appearance, as well as to distinguish lesion borders and infiltration into the surrounding tissue. Another major concern of *in vivo* breast MRS is the spectral overlap, in particular the dominant peaks due to lipids. To address this issue, Thomas *et al.* have carried out localized two-dimensional correlation spectroscopy experiments [66] and have shown that the W–F ratio can be calculated using two-dimensional spectral peak volumes. In addition, peaks due to unsaturated fatty acids can also be differentiated from saturated fatty acids. The TCho signal can also be used to monitor tumor response to different therapeutic regimens [22,56]. In a study carried out in our laboratory on 44 infiltrating duct carcinoma patients, the TCho peak was either reduced or absent after the third and/or sixth cycle of neoadjuvant chemotherapy [22].

Future Directions and Conclusions

Results obtained to date indicate that the sensitivity of MRS may be limited by various technical factors rather than by intrinsic properties of the tumors. Therefore, any improvement in signal-to-noise ratio that will effectively enhance the detection of TCho resonance may increase the sensitivity and improve the diagnostic potential especially in relation to ^{1}H MRS. Moreover, the detection of choline signal can be increased by performing MRS at higher fields [24,55]. Use of special radio frequency pulse sequences, like simultaneous suppression of water and lipid signals that are specifically optimized for detection of the signal at 3.2 ppm, would also improve the sensitivity of detection of TCho. Use of respiratory-gated radio frequency sequences would improve motion related artifacts. In addition, advances in the design of MR coils should improve detection of TCho. Use of metabolic imaging will also allow exploration of tumor heterogeneity and characterization.

Currently, breast MRS is not routinely performed as part of a breast MRI examination in many centers, in part because it is technically challenging and time consuming. More research focusing on early diagnosis with improved sensitivity and specificity and evaluation of response to chemotherapeutic agents in breast cancer patients would be clinically useful. Presently, MRS and MRI are complementary tools to histology, mammography, and other accepted techniques. Increasing use of these methods is expected for basic research, clinical investigations, and ultimately for patient diagnosis. The sensitivity and specificity of *in vivo* MR particularly for small lesions needs to be improved before MRS can be incorporated into clinical practice.

Acknowledgments

The financial grant (SP/S0/B27/95 and SP/S0/B21/2001) to NRJ from the Department of Science and Technology, Government of India, is gratefully acknowledged. We wish to thank Prof. G. Govil for critical evaluation of the manuscript and for many useful suggestions. The authors thank Drs. Mahesh Kumar, V. Seenu, O. Coshic, S.N. Dwivedi, Profs. A. Srivastava, P. K. Julka, G.K. Rath, Dr. Stefan Roell, and Mr. Virendra Kumar for their support and help.

In Vivo Molecular MR Imaging: Potential and Limits

Mathias Hoehn and Uwe Himmelreich
In-vivo-NMR-Laboratory, Max-Planck-Institute for Neurological Research, Cologne, Germany

Introduction

The recent years have seen dramatic progress in molecular imaging across the board of various techniques. Molecular imaging, in the context of the authors' goals in this chapter, is termed as the non-invasive, *in vivo* visualization of cellular and molecular events in normal and pathological processes. In particular, optical and *in vivo* bioluminescence imaging (BLI) techniques [1,2] but also positron emission tomography (PET) [3,4] have set the pace. All these high-resolution imaging modalities are based on the same general idea that the presence of specific contrast agents, incorporated or intracellularly induced by cellular activities, will provide the necessary contrast of the cells or compartments of interest against the background of the host tissue [1,5].

For the purpose of specific contrast generation, either tracers or contrast agents are incorporated in cells or attached via selective antigen–antibody bindings. Alternatively, cells are, in close cooperation with molecular biologists, transfected with the goal of expressing selected markers. These markers are considered "reporter genes," as the genes responsible for the marker expression are coupled to other predefined genetic expression patterns. Thus, the reporter genes can be chosen to be expressed constitutively (i.e. permanently) or conditionally (i.e. dependent on specific gene activities, linked to particular cellular dynamics or functional activity).

Magnetic resonance imaging (MRI) has joined this group of imaging modalities with cellular/molecular focus only very recently. The reason for this "late appearance" as a player in the field of molecular imaging, despite its high spatial three-dimensional (3D) resolution, is based on the fact that labeling strategies of cells for this imaging technique are not as intuitively available and not directly accessible. For example, optical techniques exploit very successfully the existence of naturally occurring chromophores, genetic code of which is transfected in a selected group of cells. The most successful single chromophore to date is probably the green fluorescent protein "GFP," originally found in certain jellyfish.

For MRI applications of microscopic resolution and for the study of cellular dynamical processes, cells can be effectively loaded with iron oxide nanoparticles. This cell loading generates a pronounced contrast in T_2^*-weighted images. This approach is by now well established and has already led to a variety of applications in diverse medical but also in developmental biological areas. In the latter field, individual cells of an embryo have been labeled [6,7] and, consequently, the fate of the labeled cells during further cell division and selective cell migration was followed *in vivo*. In the medical arena, there are two major application fields: one dealing with the monitoring of macrophage activity during inflammatory processes in various organs including liver [8,9] as well as brain [10–12] and another field dealing with stem cell implantation in the hope of successful tissue regeneration [13–16] (Figure 1).

This chapter is not aiming to review the broad application field. For this purpose, the reader is referred to a couple of excellent recent reviews [17,18]. The basis for the success of these applications in animal models rests in all cases on fundamental considerations concerning the reliable detectability of the cells of interest and the monitoring of their fate in space and time. The present chapter will review the methodological and technical aspects of the ultrahigh-resolution MRI technique, and, most of all, the key tool of this strategy: cell labeling. The goal of the present chapter is to provide the reader with an insight into the methodological requirements for successful *Molecular MRI*, and to prepare an overview of the various strategies from which the reader is then free to determine an optimal strategy for particular applications.

Detectability

Intrinsic contrast is in most cases insufficient to monitor cells *in vivo*. Cell-specific contrast must be generated in order to distinguish between targeted cells and other tissue or cells. Generation of sufficient contrast depends on (a) the availability of high-affinity contrast agents, (b) the ability of these contrast agents to overcome biological delivery barriers (e.g. cell membranes; blood–brain barrier), (c) minimal disturbance of the cellular microenvironment (low toxicity), (d) amplification strategies that result in appropriate concentrations, and (e) the availability of sensitive, high-resolution imaging techniques. Cells can be labeled *in vivo* or by pre-labeling, *ex vivo*.

Paramagnetic MRI contrast agents modulate the spin–lattice relaxation time (T_1) of rapidly exchanging water

Migration of embryonic stem cells in ischemic rat brain
6 days after implantation
8 days after implantation

Fig. 1. Coronal sections through a rat brain at 6 and 8 days following implantation of embryonic stem cells into the left hemisphere, contralateral to the induced transient 60 min focal cerebral ischemia. 3D data sets were recorded with isotropic spatial resolution of 78 μm with a scan time of approximately 70 min. The primary implantation sites in the cortex and the striatum are indicated by white arrows. Note at 6 days, the discrete dark line (dark arrow) along the corpus callosum between the cortical implantation site and the ventricular wall showing cells migrating toward the lesioned hemisphere. At 8 days postimplantation, a dark region becomes visible in the dorsal part of the lesioned territory reflecting the first arrival of USPIO-labeled cells.

molecules and alter the local homogeneity of the magnetic field (T_2 and T_2^* relaxation times). Cells labeled with contrast agents generate *hypo*intense contrast in T_2-weighted (T_2w) images (labeled e.g. with iron oxide particles) or *hyper*intense contrast in T_1-weighted (T_1w) images (labeled e.g. with Mn or lanthanide chelates). These contrast agents most commonly consist of nanoparticles (iron oxide, T_2w), inorganic chelates (Gd, Eu, and Mn chelates; T_1w), or particles contained in a polymer sphere (iron oxide microspheres).

A precondition for a contrast agent is that the relaxivity of exchanging/surrounding protons is sufficiently modified. The large magnetic susceptibility of small paramagnetic particles can affect much larger regions of the image than is suggested by the actual size of the particle [19]. The limits of cell detectability are defined by the spatial resolution, the signal-to-noise ratio (SNR), and the contrast-to-noise ratio (CNR).

Contrast Agents for Molecular Imaging

The suitability of magnetic markers for molecular MR imaging is influenced by the change of the MR signal caused by alterations in the magnetic susceptibility and expressed by the relaxivity (R). Contrast agents for molecular imaging must provide a high relaxivity *in vivo* without compromising the cellular microenvironment. This sets certain limitations for the concentrations of contrast agents. The choice of contrast agents also depends on the intrinsic background signal of the respective application.

Dextran coated superparamagnetic iron oxide particles (SPIOs) [20] and ultrasmall SPIOs (USPIOs) have magnetic moments more than three orders of magnitude larger than those of clinically applied contrast agents [21]. Iron oxide particles can be used for T_1- [22], T_2- [12], and T_2^*- [23] weighted imaging. Due to the large magnetic moment of (U)SPIOs, the relaxivities R_2 and R_2^* are several thousand times larger than R_1 [24]. (U)SPIOs are well suited for cell tracking because of the long-range susceptibility effects. Relaxivity (R_2/R_2^*) of iron particles can easily be tested *in vitro* by comparison of signal quench in the presence of respective contrast agents. R_2^* relaxivity increases with increasing concentrations of the iron oxide particles but will be saturated (complete quench of signal) [24–26]. Saturation of magnetization occurs once the mass of iron per cell exceeds a certain threshold [24]. When normalized to iron content, larger particles greatly decrease T_2^* and enhance the susceptibility effect when compared to smaller particles [27].

The T_2^* effect of iron oxide based contrast agents is also larger than T_1 effects of Mn- and lanthanide-chelates because water molecules must be in close proximity of the paramagnetic center to generate T_1 contrast [28]. Crich *et al.* estimated the minimum detectable number of Gd-HPDO3A labeled cells in a phantom at approximately 10^3 cells [29]. Visualization is attainable when cellular concentrations of Gd-contrast agents are in the order of 10^{-4}–10^{-5} molar [30,31].

Magnetic properties that are most commonly modified for the design of contrast agents that predominantly increase R_1 relaxivity (hyperintensity in T_1w MR images) include:

(a) hydration number (q)—water bound to agent
(b) exchange rate of water molecules (τ_m)
(c) rotational correlation time of complex (τ_r).

In order to achieve sufficient contrast with T_1w contrast agents *in vivo*, accumulation of contrast agent to millimolar concentrations is usually required [32]. A system that entraps several units of a Gd chelate is apoferritin, resulting in an increase of relaxivity by almost 20 times compared to the free contrast agent [33,34]. Other approaches to concentrate Gd chelates at the site of interest include self-assembling aggregates [30,35,36]. It was suggested in recent studies that even picomolar binding is sufficient to achieve detectable CNR if high loads of particles were delivered to the cell [37].

The rotational correlation time of a contrast agent can be altered by changing the viscosity of the environment or by interaction with large molecules [38]. The latter has resulted in the design of contrast agents that specifically bind to certain proteins [39,40].

Resolution

Low image resolution can attenuate the relaxation effects through partial volume effects and thereby reduce detectability of labeled cells. The spatial resolution is limited by the strength of the gradients and the matrix size. The acquisition of MR images with a resolution in the order of tens of microns is currently possible within a reasonable time frame. The trade-off of high resolution is a reduced SNR.

A precondition for detection of single labeled cells by MRI is that the number of voxels is higher than the number of individual cells in the respective volume. Dodd *et al.* have demonstrated a good correlation of individual cell distribution between MRI and microscopic methods, proving the detectability of single cells by MRI [41]. Larger susceptibility effects, like for micron-size iron oxide particles, result in higher contrast and permit detection at lower resolution [27,42,43]. These microspheres can be considered a point source that creates a localized field larger than the field created by the evenly distributed, smaller (U)SPIOs, resulting in detectability of single cells with a spatial resolution as low as 200 µm [42].

Signal- and Contrast-to-Noise Ratio

The dilemma of cell tracking in animal models is that acquisition time is limited and resolution has to be as high as possible in order to meet the requirements set by working with anaesthetized animals and being able to detect small numbers of cells *in vivo*. This limits the options to maximize SNR and CNR. Apart from longer acquisition times, the SNR can be increased by stronger magnetic fields, smaller RF coils, and cryoprobes [44,45]. Pulse sequences, repetition time (T_R), echo time (T_E), and pulse length have to be chosen carefully and adjusted for each animal model. Optimization of MR parameters has been reviewed extensively [46,47]. The CNR is influenced by the efficiency of the labeling strategy. Visually apparent contrast is defined as $\mathrm{CNR} \geq 5$, with $\mathrm{CNR} = |(I_A - I_B)N^{-1}|$ (I_A, I_B—signal intensities of the two adjacent regions, N—noise level). Using the relaxivity of the respective contrast agents and T_1/T_2—values of the tissue, acquisition parameters (T_R, T_E) can be optimized to maximize CNR [31,37].

It was demonstrated that detection of single cells *in vitro* is feasible [41,42,48].

Quantification

Cells can be quantified *in vitro* by the construction of simple gelatin phantoms [25,49] (Figure 2). If a sufficient spatial resolution is provided in 3D MR images and homogeneous phantoms are utilized individual cells labeled with iron oxide particles can be counted in high dilutions [49].

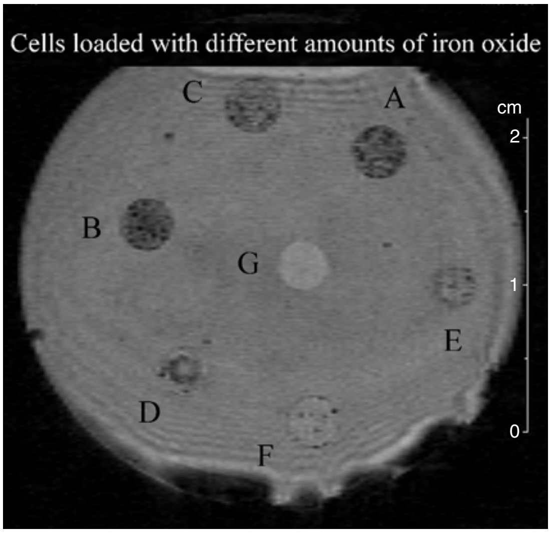

Fig. 2. Agarose gel phantom containing embryonic stem cells transfected with iron oxide particles. The holes A–E and G contain approximately 10^4 cells and the hole F contains 5×10^2 cells, which were suspended in 50 µl agarose. Cells were incubated with different concentrations of iron oxide nanoparticles prior to suspension (amount of iron oxide per 5×10^5 cells: A, 40 mg; B, 18 mg; C and F, 5 mg; D, 1 mg; E, 0.2 mg; and G, no iron oxide particles). The 3D gradient-echo MR image (FLASH) was acquired with the following parameters: field strength = 7 T, matrix = 256K × 128K × 64K data points; $T_R = 250$ ms, $T_E = 20$ ms, FOV = 4 cm × 4 cm).

Bowen *et al.* have addressed the quantification of iron oxide concentrations in cell suspensions based on relaxivities [24]. Relaxation rates of compartmentalized (U)SPIOs correlated with predicted values using the static dephasing theory [50]. Best correlations were achieved using (R_2^*–R_2) under the dilute pertuber assumption, indicating the suitability for quantification for cases where volume fractions of cells containing iron oxide are relatively small, as is the case, e.g. for implanted cells *in vivo* [24]. This model has only been tested *in vitro*. Experimentally, detection of cell clusters of tens to hundreds of (U)SPIO-labeled cells was demonstrated in animal models [14,51]. It was suggested that the utilization of micron-size iron oxide particles are suitable to detect single cells *in vivo* [52]. An additional advantage of these latter particles is that single particles or cells can be detected *in vitro* even with relatively low resolution (due to the large diameter and magnetic moment), and that the label is not diluted beyond the minimum observable threshold by cell division but remains within the cell for up to 1 year [27,43,52].

If the relaxivity of lanthanide contrast agents is known model-based predictions of local concentrations of T_1 contrast agents can be reliably performed by measurement of T_1 values [31,37]. If particle loading of cells and relaxivity of the contrast agent remain constant after implantation this could result in quantitative MRI in *in vivo* models. Contrary to these results, Crich *et al.* have found that cell pellets with variable Gd-chelate loading show a decrease of R_1 relaxivity if concentrations exceed 0.1 μmol/mg protein [29]. Possible explanations include competing T_2^* effects, resulting in signal broadening.

Cell Labeling

Route of Uptake

Conventional MR cell labeling relies on surface attachment of contrast agents to the cell [53–56]. Contrast agents are often chemically modified so that they bind unspecifically or to specific cell types. A common strategy involves linking a contrast agent with a monoclonal antibody that is recognized by receptors on the cell surface [55]. For review see Ref. [30]. These strategies are generally not suitable for *in vivo* applications, where interactions with other cells have to be avoided, as for stem cell tracking. Extracellular labeling may result in detachment of the label or transfer to other cells. We will therefore focus on strategies to internalize contrast agents.

Probably the most effective route to internalize compounds into cells is by endocytosis. Hereby, intracellular vesicles (endosomes) are formed after introflection of portions of the cell membrane and fusion of its extremities. The endosomes contain compounds that are either bound to the membrane or present in the extracellular medium. Endocytosis is most effective in phagocytic cells (also called phagocytosis). Paramagnetic iron oxide particles but also Gd chelates have been successfully internalized into macrophages, monocytes, mononuclear T-cells, and oligodendrocyte progenitors [13,26,29,57–61]. In order to internalize high quantities of a contrast agent, receptor-mediated endocytosis is sometimes the method of choice. Hereby, the substrate in the extracellular medium interacts with receptor molecules on the membrane (like contrast agents linked with a monoclonal antibody) and are internalized in high concentrations [26,62].

Hinds and co-workers [27,43] have demonstrated that even micron-scale particles (0.9–2.8 μm) of an aggregate of iron oxide magnetite that is encapsulated in a polymer, are incorporated into perinuclear endosomes by stem and progenitor cells [48]. This labeling strategy has been highly efficient (almost 100%). It was also found that concentrating (U)SPIOs into cells increases the relative R_2^* sensitivity, compared to uniformly distributed particles [26,63].

In order to increase the uptake of contrast agents that do not spontaneously accumulate in endosomes, magnetoliposomes [64], and lectins [65] have been used in several experiments. A method developed in molecular biology for transfection of oligonucleotides, lipofection has been successfully adopted for labeling of cells with contrast agents [14]. Commercially available polycationic transfection agents encapsulate (U)SPIOs through electrostatic interaction [66]. The transfection agents shuttle the (U)SPIOs into the cell and form endosomes that finally merge into liposomes. This procedure has successfully been applied for labeling T-cells, stem cells, and other mammalian cells [14,66–69]. A similar approach is the labeling of cells with magnetodendrimers, which consist of (U)SPIOs coated with carboxylated dendrimers [51]. These compounds are also used as transfection agents and result in the formation of endosomes [70]. A broad range of cells has been labeled with dendrimers [15,51,71,72].

Others have produced transgenic cells expressing, for example, the transferrin receptor and are thus susceptible to the uptake of conjugates of transferrin and monocrystalline iron oxide nanoparticles [73,74].

Many larger probes are membrane impermeable and fail to attain intracellular concentrations required for MRI. Peptides or proteins mediating membrane translocation signals (MTS) have been coupled with contrast agents for internalization. MTS from the HIV tat peptide have been linked to SPIOs and lanthanide chelates for transport into several cell types [75–78]. Hereby, the contrast agents most likely accumulate in the cytoplasm [77]. Allen and Meade have suggested a relatively simple system for internalization that consists of a polyarginine-modified Gd DOTA system [79].

Microinjection of contrast agents was used in embryology for cell tracking [6,7]. Increased contrast was detectable in the developed embryo compared to controls, indicating sufficient contrast with cell division. However, this method has only applications limited to injection of large single cells in developing embryos. It is not practical for tracking populations of cells due to its labor-intensive preparation and the dilution of the label with cell division [7].

Zhang *et al.* adopted another method from molecular biology, where so-called biolistic "gene-guns" are used to introduce oligonucleotides into cells [80,81]. Biolistic labeling was performed with ferromagnetic particles and resulted in a labeling efficiency of 95% of surviving cells. Similarly to microinjection, cell labeling remained stable.

Electroporation is a process that permeabilizes cell membranes by exposure to an external electric field. Rapid resealing of the membrane pores traps internalized compounds inside the cell. Widely used to introduce foreign DNA into cells, it has also been used for drug delivery [82]. Paturneau-Jouas *et al*. have used electroporation for the uptake of low-molecular weight Gd chelates *in vivo* [83]. It remains to be seen how efficient this labeling method is and how stressful it proves for the respective cells.

In vivo and *ex vivo* Labeling

In vivo labeling of cells is possible if phagocytes take up contrast agents that were administered either intravenously or after injection in the targeted organ. This labeling strategy is based on naturally occurring or targeted, mediated endocytosis (mainly macrophages). Hereby, macrophages accumulate the iron oxide particles from the blood, whereas the remaining iron oxide in the blood (or other organs) is washed out. It was first introduced for hepatic imaging [84]. Subsequent development of clinically approved USPIOs have resulted in labeling strategies to distinguish between normal tissue and tumor metastases in lymph nodes [85] and bone marrow [86] based on the uptake of these particles by macrophages in those organs.

The uptake of iron oxide by macrophages has also been utilized in some disease models to highlight increased macrophage activity in areas of inflammation. Such applications include visualization of atherosclerotic plaques [87], visualization of increased macrophage activity in the kidney after injury and organ rejection [88,89], and macrophage infiltration in brain lesions following ischemia [10,90].

Direct injection of micron-size iron oxide particles into various regions of the sub-ventricular zone of the rat brain resulted in *in vivo* labeling of neuronal stem cells by endocytosis, allowing their migration to be tracked along the rostral migratory stream to the olfactory bulb [52]. Coupling of MTS peptides with nanoparticles and antibody or receptor binding ligands has been suggested as a possible targeted *in vivo* labeling strategy [91]. Paturneau-Jouas *et al*. have used electroporation after intraperitoneal injection of Gd chelates for internalization into muscle cells *in vivo* [83].

So far, targeted *in vivo* labeling was mainly demonstrated for phagocytes. In all other cases, pre-labeling of cells according to the procedures listed above is necessary. Hereby, *in vitro* pre-labeled cells are transferred to the targeted organ or tissue by injection.

Responsive Contrast Agents

Contrast agents have been developed with the aim of reporting on the physiological status and metabolic activity of cells [30,92]. Most of these contrast agents are Gd based chelates with one or more potential coordination sites blocked in the inactive state, preventing free access of exchanging water molecules to the paramagnetic ion.

Lowe *et al.* synthesized an MR contrast agent that is responsive to changes in pH, generating no contrast at high pH but high contrast at low pH [93]. The Gd DO3A derived agent contains a sulfonamide nitrogen, which is protonated at low pH. Therefore, it cannot coordinate at low pH and provides free access to exchanging water molecules. Meade and co-workers developed a probe that is responsive to intracellular changes in calcium concentrations [94,95]. Similarly, two carboxyl groups of the chelate coordinate either to the Gd^{3+} ion (inactive) or to the Ca^{2+} ion (active). Probes responsive to enzyme activity (e.g. β-galactosidase) have been developed [96] and applied for cell visualization *in vivo* [6]. Contrast agents responsive to pO_2 were developed on the basis of the BOLD effect [97] and coupling an increase in τ_r with and redox switch [98].

Other contrast agents utilize the so-called chemical exchange saturation transfer (CEST) agents to be responsive to variable concentrations of targeted molecules [99,100]. Aime *et al*. have suggested an insoluble contrast agent that is activated by intracellular enzymatic solubilization [30]. However, the effective incorporation of the contrast agent in its insoluble state is still an unresolved issue.

In vivo MRI Experiments

Cell tracking *in vivo* requires the acquisition of isotropic 3D MR images of living animals at near-cellular resolution in order to minimize partial volume effects. Temporal constraints are set by working with live animals so that spatial resolution is typically in the range of tens up to a hundred of microns. The principle challenge is to obtain sufficient SNR. Hardware improvements often target the reduction of thermal noise voltages from the sample by using small surface RF coils [101]. Design of the receiver coil aims for low coil resistance. This can be achieved by cryo-cooled probes [102], which have been applied to micro-imaging in animal models [44,45]. RF coils made of high temperature superconducting material have also been demonstrated to reduce coil loss substantially *in vitro* and in animal models [103,104].

Animal models require usually anaesthetized animals. Apart from the obvious associated disadvantages, it has the advantage of decreasing movement artifacts in MR images as the animal can be firmly fixed in an animal holder.

MRI of animal models is usually performed at a high field strength (>4 T). While this is an advantage for improving the SNR it has the disadvantage of an increase in the T_1/T_2 ratio, resulting in an increase in the acquisition time and in a loss of intrinsic contrast in the brain. The increase in the magnetic field strength, compared to clinical systems, also results in more pronounced magnetic susceptibility effects. While this can lead to unwanted artifacts in the MR images, it has also the advantage that magnetically labeled cells can be more easily visualized. Gradient-echo sequences tend to be more susceptible to those artifacts than spin-echo experiments.

Data acquisition methods utilized for cell tracking are similar to those employed for clinical MRI (spin-echo, gradient-echo, diffusion-weighted imaging, inversion recovery, and magnetization transfer sequences). Rapid acquisition methods are commonly used for animal models, namely gradient-echo fast-low-angle-shot (FLASH) [105] and echo planar imaging (EPI) [106]. The utilization of MR microscopy for animal models was reviewed by Ahrens *et al.* [107].

Pulse sequences that emphasize signal loss due to field inhomogeneities are beneficial for (U)SPIOs. Cell tracking in animals is usually performed using 3D gradient-echo sequences (FLASH) for T_2/T_2^* effects [14,51,62] and two-dimensional (2D) multi-slice or 3D spin-echo sequences for T_1 effects [6,29,57]. Unless very strong T_1 weighting is used with T_Rs of approximately 100 ms, spin-echo sequences are not fast enough to permit the acquisition of a high-resolution 3D image within the time frame required for anaesthetized animals. 2D multi-slice images have the disadvantage of strong partial volume effects. A resolution of 100 to 200 μm is usually sufficient for the visualization of small cell clusters. The detection of single cells is not realistic as naturally occurring movements like breathing and muscle twitching are in the order of hundreds of microns, resulting in blurring effects. Additional blurring effects are caused by diffusion [41]. The acquisition of 3D data sets is, at any rate, a requirement for the co-registration of data sets in longitudinal studies and for the co-registration with independently recorded, non-MR data sets.

The effects of gradient strength, T_R and T_E to optimize SNR and CNR in MRI have been studied extensively [41,46,47]. For conditions of large magnetic moments due to (U)SPIOs loaded cells in animal models, the greatest sensitivity was observed with R_2^*, rather than R_2 or R_1[24]. Low gradient strengths through the use of low acquisition bandwidths will enhance susceptibility effects. This is also beneficial in terms of SNR, due to reduced diffusion loss.

An intrinsic problem for tracking iron oxide labeled cells in animal models are other areas of susceptibility induced field inhomogeneities (signal loss in T_2/T_2^*w images), namely from airspaces, but more importantly, from blood clots/hemorrhages and tissue interfaces. Seppenwoolde *et al.* have developed a technique that exploits the natural dipolar field surrounding paramagnetic markers by introducing a dephasing gradient on the slice-select axis to spoil signal across all the sample except in regions where the local gradients surrounding the paramagnetic marker are of the right amplitude and orientation to combine constructively with the added dephasing gradient to result in refocusing of the lost signal [108]. Coristine *et al.* have applied this "white-marker" technique to distinguish iron oxide labeled cells from other sources of field inhomogeneities [109].

The optimal acquisition parameters need to be determined for each combination of cell type, animal model, and contrast agent.

Biological Aspects of Cell Labeling

Reproducible and efficient visualization of cells with MRI does not only require optimized MR properties of contrast agents but also biological properties that result in stable labels without affecting other cellular processes.

Toxicity

Many contrast agents are administered in coated (polymer coating) or chelated (in particular the lanthanides) form, in order to reduce toxicity. Commercially available and clinically tested contrast agents are often used for molecular imaging, for which short and medium term toxicity is minimal. However, one has to consider that contrast agents for molecular imaging are often applied for longitudinal labeling, and in concentrations much higher than clinically applied. Immediate toxic effects can easily be tested by growth and viability studies in cell suspensions. It is more difficult to assess long-term stability (and toxicity) of coated contrast agents and the effect of contrast agents on cellular processes like differentiation.

It has been reported that very high concentrations of (U)SPIOs for cell labeling (up to 2 mg iron/ml) can cause decreased proliferation and even cell death [110]. This is in particular true after the formation of reactive oxygen species [111]. Some dextran coatings for iron oxide particles are biodegradable [112]. Released iron enters into the cellular iron metabolic pathways. Iron in high concentrations is known to interact with a number of other metabolic pathways [113,114]. Overloading can result in increased oxidative stress. Although iron oxide can be released by biodegradation, one has to consider that this will occur gradually resulting in non-toxic free iron concentrations. Stroh *et al.* have found that decomposition of the coating of iron oxide particles does not affect cell growth but causes oxidative stress [113]. These authors have suggested the application of antioxidants or iron chelators to prevent toxic effects of leaking iron.

T-cells labeled with SPIOs by endocytosis retain their function [58,115]. Sapiro *et al.* have shown in longitudinal studies that even large iron oxide loaded microspheres do not influence cell proliferation and differentiation at low concentrations [48,52]. Hill *et al*. found a dose-dependent alteration in cell proliferation but not in differentiation for mesenchymal stem cells [43]. Also, magnetodendrimers and (U)SPIOs did not cause differences between labeled and unlabeled cells in terms of proliferation, viability, and differentiation of neural stem cells in short term *in vitro* experiments [14,51,71]. Frank and co-workers have studied the effect of superparamagnetic iron oxide nanoparticles and transfection agents extensively [67–69,116]. No long-term effect on cell viability, rate of apoptosis, phenotype, proliferation, activation, and differentiation was found.

The toxicity of lanthanide contrast agents has also been studied extensively [38]. As lanthanides are known to be highly toxic, stable chelates are required for protection. Gd-HPDO3A is one of the best tolerated contrast agents with an $LD_{50} > 10$ mmol/kg in rats [38]. Although well tolerated in clinical applications, high dose toxicity for molecular imaging application requires further investigations. Several studies have confirmed that Gd-dextrans remain intact in cells [29] and are tolerated by cells in culture and *in vivo* after implantation [13,29,57].

In addition to metal ions, the interactions of chelates, transfection agents, or antibodies have to be considered for the assessment of toxicity. Although concern has been raised about potential release of reactive iron species from tat-labeled cells [67], functional tests with and without HIV tat peptide based contrast agents have shown no difference between labeled and unlabeled cells [77]. When used alone, some transfection agents are reported to be toxic [116]. However, iron oxide complexed with transfection agents does not affect viability, differentiation, or proliferation [68,69,116]. It was found in one study that the differentiation of stem cells can be influenced by transfecting agents [117]. This highlights the need to study possible biological side effects for each labeling system and cell type.

In addition to toxicological aspects of the contrast agent, one has to consider that labeling procedures like electroporation, microinjection, or biolistic "gene-guns" can cause mechanical damage to cells.

Assessment and Stability of Label

It is crucial for *in vivo* cell tracking to estimate the efficiency of cell labeling, the internalization of the label, and for how long these cells are detectable (i.e. dilution of the label; Figure 3). Various approaches have been taken to assess *in vitro* labeled cells by using agar or gelatin based phantoms (Figure 2).

It was found that uptake of (U)SPIOs as well as Gd chelates by endocytosis is linear with dose [24,29]. Linearity was also shown for (U)SPIO uptake with incubation time [24,118]. Interestingly, uptake is increased with particle size [118], which also explains the excellent uptake of micron-size microspheres [27,48].

The labeling efficiency can be assessed by NMR relaxometry [29,30,7,78] or by other techniques like atomic absorption spectroscopy to determine the iron content of USPIO-labeled cells [14]. Internalization of contrast agents (Figure 3) can also be verified by staining techniques in combination with (electron) microscopy.

The visibility of cells with time depends primarily on the dilution of the contrast agent due to cell proliferation and on degradation processes of the coating of contrast agents. Stem cells labeled with iron oxide particles have been monitored *in vivo* for up to 7 weeks in rat brains [14] and for up to 3 months in a spinal cord implantation model [72]. Embryonic stem cells were detectable, with contrast condition comparable to the originally labeled culture, after 20 cycles of cell division, which is an increase of cell numbers by a factor of 10^6 [14,25,49]. In another study, the complete disappearance of iron particles has been observed due to dilution after proliferation within 2–3 weeks [69].

An advantage of large micron-size particle is that a single particle per cell may result in sufficient contrast. Hill *et al*. were able to detect mesenchymal stem cells for up to 3 months [43]. Shapiro and co-workers monitored microsphere labeled cells for 1 year [52].

Cell labeling with lanthanide chelates is more affected by dilution after cell division due to its lower sensitivity. Modo and co-workers were able to visualize stem cells for up to 7 days after labeling with a Gd chelate [13].

Histological evaluation at the endpoint of longitudinal MR studies is necessary to evaluate MR tracking of cells *in vivo*. Other causes for loss of label are exocytosis (Figure 3) and immune reaction with a subsequent transfer of contrast agents to macrophages. Co-location can be estimated by co-registration of MR images with stained histological sections. Due to the invasiveness of histological methods, co-registration with MR images will always be problematic due to swelling, distortion, etc. Possible approaches include corroboration of MRI detection of labeled cells by using Prussian blue staining against iron [62], validation with X-gal staining [51], or electron-dense inclusions for visualization by electron microscopy [61]. In addition, dual staining detects co-localization of contrast agent with certain cell types. An example is the Prussian blue and $ED1^+$ staining to discriminate USPIO-labeled macrophages [10,119].

The use of bifunctional contrast agents allows co-registration of histology and MRI without recourse to other methods. Dual labeling strategies can be classified in methods that use dual contrast agents and methods that utilize cells that can be visualized by specific modalities (e.g. cells that express certain proteins). Modo labeled stem cells with a Gd-Rhodamine dextran (GRID) that is

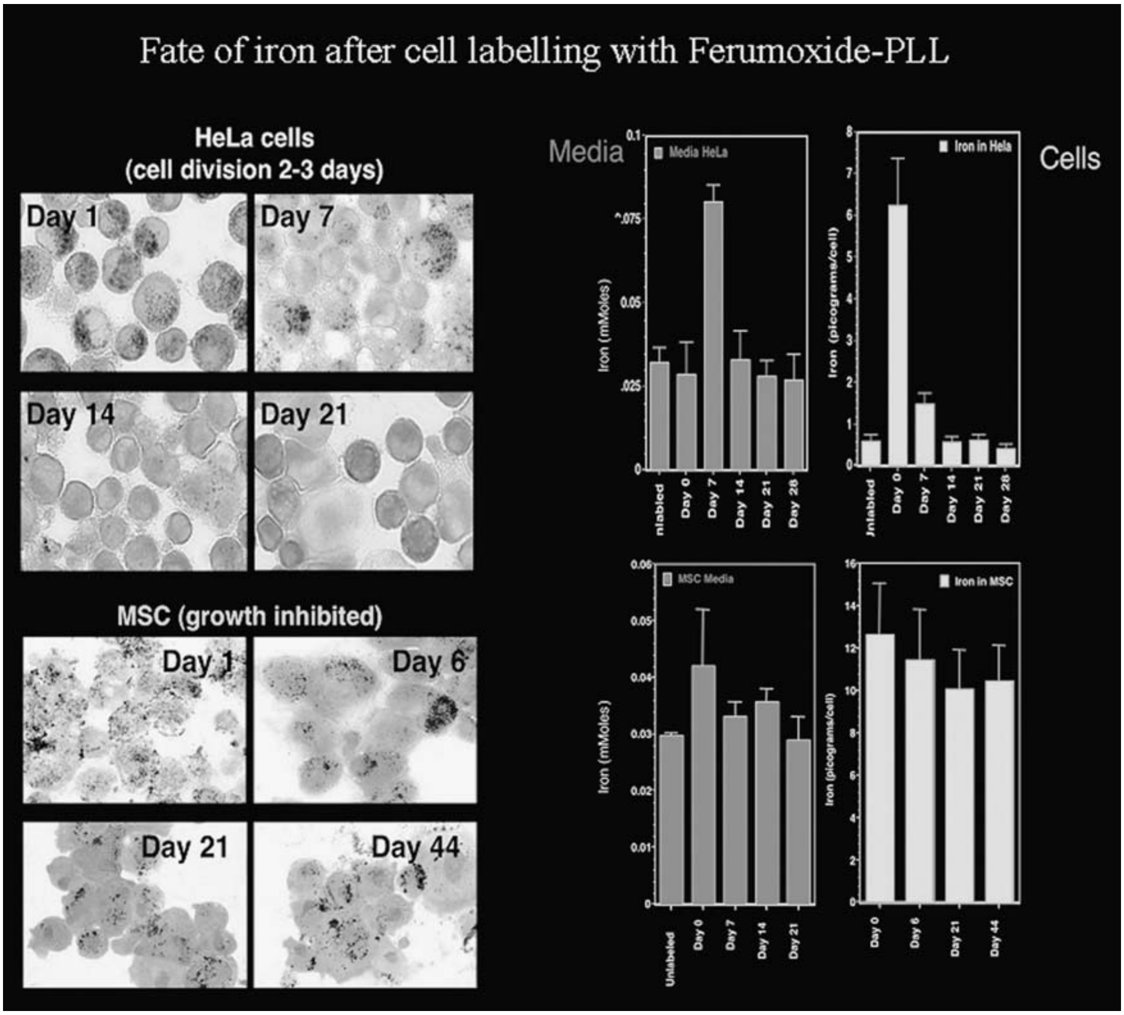

Fig. 3. Investigation into the persistence of iron oxide label after incorporation into HeLa cells or mesenchymal stem cells (MSC). On the left side, Prussian blue staining of cell cultures is depicted at various times after cell labeling. It is clear that the blue stain reflecting the iron content is rapidly lost in the heavily proliferating HeLa cells, while dark blue stains are still detected in the (very little proliferating) MSCs even after 44 days. The bar diagrams on the right show the iron content as determined in the cell culture medium (red) and in the cells (yellow), with the situation for the HeLa cells above, and the MSCs below. Again, the iron content remains quite stable for the MSCs, both in the cytosol and in the media. The HeLa cells have a maximum of iron directly following labeling, which is rapidly lost again (by leakage). This is reflected in the medium where the iron content transiently increases during the phase when the cells lose their iron content. Modified with permission from Ref. [69]. (See also Plate 89 on page XVI in the Color Plate Section.)

both magnetically and fluorescently detectable [13,57]. Hereby, MRI results can be assessed by subsequent fluorescence microscopy on histological sections. In addition, fluorescence microscopy allows additional staining to detect co-localization with markers for cell differentiation [13].

Similarly, labeling with Mn^{2+} as contrast agent allows validation by an independent method. Mn^{2+} has been used as an *in vivo*, trans-synaptic, MRI-detectable neuronal tract tracer that enters selectively neurons via Ca^{2+} channels [120–122]. The fate of Mn^{2+} can be verified by independent fluorescent dye staining.

Similar approaches, combining iron oxide particles with fluorophores were taken to track stem cells *in vivo* [27,43]. In contrast to dual contrast agents, co-localization can also be achieved by labeling stem cells that express fluorescence properties with USPIO [14]. These genetically modified stem cells express the GFP that can be detected on histological sections. In contrast to the other approaches, only those cells show fluorescence that is still viable at the time of termination. Hereby, dead cells and cells whose label had been transferred to macrophages can be distinguished from the targeted cells.

Summary

In summary, the successful design of a molecular imaging study of cells by MRI depends on a series of methodological evaluations and optimizations. As several of these optimization steps will prove to be dependent on the particular circumstances of the investigation, a checklist of aspects to be assessed before *in vivo* experiments are started can be compiled and is given here.

1. Select contrast agent dependent on intrinsic background (e.g. signal loss vs. signal gain),
2. optimize internalization of contrast agent,
3. check residence duration of contrast agent in cells/dilution of label,
4. check toxicity of label/labeling procedure,
5. consider independent/dual (e.g. in combination with optical) labeling options, generated by cells or co-localized on contrast agent,
6. relaxivity of labeled cells *in vitro,*
7. MRI sensitivity, and
8. hardware optimization for scan-time minimization.

As some of these considerations and tests will vary very much with cell type, disease model, etc. it is always advisable to perform the respective assessments anew when new cell lines or animal models or contrast agent is considered for use.

Outlook

With a more widespread application of cell labeling, the above discussed procedures will become more routine and established for a broad range of cell lines and applications. An integrative view on sensitivity improvement of MRI systems will most likely lead to voxel sizes reflecting a handful of cells, under true *in vivo* conditions, compatible with scan times that result in anesthesia periods tolerable for weakened animals of various disease models, in longitudinal investigations.

A close interaction between specialists of three different disciplines is seen as the basis for the exciting contributions of *in vivo* molecular MRI in the future. Expertise in *in vivo* MRI, including the understanding of animal physiology and pathophysiology, is a central prerequisite. The second partner will contribute expertise in contrast agent chemistry to design and synthesize the new generation of so-called “smart contrast agents.” These could be agents that are activated or deactivated under external control or under control of the cell status. Finally, the third discipline is molecular biology to design transgenic cells, so-called “smart cells.” These cells will be able to activate or deactivate added smart contrast agents according to the selected reporter gene. Alternatively, such transgenic cells may even produce their own intracellular contrast agent, as has recently been shown in an impressive investigation by the laboratory of Neeman [123], where cells under TET-on/TET-off switches could be shifted between modes where they either produced a strong T_2 contrast or not. In the activated mode, these cells upregulated the intracellular iron depot ferritin, resulting in (non-toxic) massive accumulation of iron in the cell.

The use of MR reporter genes that are genetically expressed and generate contrast coupled to the regulation of genes or by the presence/absence of exogenous substrates opens new doors for the non-invasive analysis of cell functions in various animal models under true *in vivo* conditions. In conclusion, with the synergy of the above-described three complementary disciplines, molecular MR imaging is only beginning to explore its own potential for future biomedical studies on cellular and molecular levels.

Acknowledgment

Financial support of the Hertie-Foundation and of the German-Israeli Cooperation project by the German Ministry of Education and Research (BMBF) is gratefully acknowledged. UH gratefully acknowledges an international reintegration grant (#013080) by the European Commission.

Glossary of Terms

Contrast agent—Chemical compound that increases the intrinsic contrast in an image.

Bifunctional contrast agent—Contrast agent that increases the intrinsic contrast for two different imaging modalities.

Responsive contrast agent—Contrast agent that conditionally increases the intrinsic contrast (depending on the change of environmental conditions like enzyme activation, pH change, change in ion concentration, and others).

Dendrimers—Large and complex polymers of a consistent size and a regular and highly branched architecture.

They are often used for the encapsulation of smaller molecules.

Endocytosis—In endocytosis, the cell engulfs some of its extracellular medium including material dissolved or suspended in it. A portion of the plasma membrane is invaginated and pinched off forming a membrane-bound vesicle called an endosome.

Endosome—Vesicle formed during endocytosis.

Molecular imaging—Non-invasive, *in vivo* visualization of cellular and molecular events in normal and pathological processes.

Stem cell—Cell with broad differentiation potential that retains the capacity for unlimited self-renewal. A totipotent stem cell has the ability to differentiate to all cell types of an organism, whereas a pluripotent stem cell produces many but not all cell types.

Transfection—A method by which experimental DNA (or in our case contrast agents) can be incorporated into mammalian cells after interaction of the encapsulating transfection agent and the cell membrane.

In vivo ^{13}C MRS

Stefan Bluml
Childrens Hospital Los Angeles, Department of Radiology, USC Keck School of Medicine Los Angeles, CA

Abbreviations: MRS = Magnetic Resonance Spectroscopy; MRI = Magnetic Resonance Imaging; SNR = Signal-to-noise ratio; RF = Radiofrequency; FDA = federal drug administration; SAR = specific absorption rate; B_1 = magnetic field of RF coil; NOE = nuclear Overhauser effect; VOI = volume of interest; LCModel = linear combination of model spectra; TCA = tricarboxylic acid; Glc = glucose; Glu = glutamate; Gln = glutamine; Asp = aspartate; NAA = N-acetylaspartate; GABA = γ-amino butyric acid; Lac = lactate; Ala = alanine; HCO_3^- = bicarbonate, Ac = acetate; KD = ketogenic diet.

Introduction

The application of ^{13}C Magnetic Resonance Spectroscopy (MRS) for basic research/medical applications is challenging and, despite being available for more than 25 years, only a few groups have attempted ^{13}C MRS *in vivo*. However, the few studies undertaken illustrate the great promise of *in vivo* ^{13}C MRS. Interest in ^{13}C MRS has grown considerably in recent years. The potential of ^{13}C arises from its biggest handicap: Low natural abundance [and the compromised sensitivity (≈1/50 of ^{1}H)] renders ^{13}C spectroscopy *in vivo* very difficulty due to the inherently very low signal-to-noise ratio (SNR). This low natural abundance, on the other hand, is the key to new, exciting applications of *in vivo* MRS: Investigation of metabolic pathways and the measurement of flux rates *in vivo* in animal and humans after ^{13}C enriched substrate infusion. The interested reader is referred to a recent issue of *NMR in Biomedicine* [1] exclusively dedicated to the application of ^{13}C MRS to study biological systems for a more detailed update on progress in ^{13}C MRS than given below. Instead, in this chapter, basic experimental procedures of *in vivo* ^{13}C MRS, with emphasis on experimental work in humans, are illustrated and discussed for the researcher interested in conducting similar experimental work in the future.

Methods

Equipment

A list of additional equipment needed beyond that required for MR imaging or ^{1}H MRS is provided in Table 1.

Radiofrequency (RF) Coils

Even for “niche” manufacturers, ^{13}C RF coils are too “exotic” and most groups conducting *in vivo* ^{13}C research have built their own coils. Volume coils are more flexible and have a special advantage when quantitation of cerebral metabolites is the goal. Nevertheless, surface coils have exclusively been used for ^{13}C MRS since they furnish the much-needed extra signal required for *in vivo* ^{13}C MRS. Because all ^{13}C methods either apply direct detection with proton-decoupling, polarization transfer, or heteronuclear editing, dual-tuned coils (^{1}H and ^{13}C frequencies) are required. Two concentric circular surface coils, a small ^{13}C coil and a larger ^{1}H coil, have been used by several investigators. However, the need to block the ^{1}H flux of the inner ^{13}C coil resulted in poor performance of the ^{1}H coil in the sensitive volume of the ^{13}C coil. A much improved assembly of two semi-orthogonal surface ^{1}H coils, operated in quadrature mode, and a single linear ^{13}C coil (Figure 1) was first introduced by Adriany and Gruetter [2] and has since been adopted by other groups [37]. The quadrature ^{1}H coil assembly offers twofold improved efficiency over linear-polarized coils in the power requirement. This is important to avoid excessive power RF absorption by tissue during *proton-decoupling* (see below).

Broadband Excitation/Detection

Even if dual-tuned RF coils are available, not all magnetic resonance imaging (MRI) scanners can progress beyond ^{1}H excitation and detection. Broadband amplifiers covering the frequency of ^{13}C are essential. Similarly, RF receivers tuned to the ^{13}C resonance frequency must be provided along with several other hardware features.

Table 1: Equipment needed for ^{13}C MRS beyond that required for standard MR imaging

Hardware	Purpose	Specifications/comments
RF Coil	^{13}C and ^{1}H excitation, receive, editing, decoupling	Dual-tuned ^{13}C-1H coil, ^{13}C surface coil/surface coil assembly, quadrature ^{1}H coil for efficient decoupling
Broadband capabilities		
Broadband receiver	To digitalize, filter, and store RF signal at ^{13}C frequency	Low noise figure
Transmit/receive switch for ^{13}C with pre-amp	Protects ^{13}C receiver from high power RF during excitation, boosts the gain of the ^{13}C signal during receive	Low noise figure ($<$0.60 dB), high gain ($\sim$35 dB) pre-amp. May be supplemented with a simple gain block to provide further enhancement of the signal. A proton trap or filter (for ^{13}C a low-pass design is acceptable) placed directly before the pre-amp to limit saturation of the device and subsequent reduction in ^{13}C SNR.
Broadband exciter[a]/amplifier	Create/amplify RF pulses at ^{13}C frequency	Minimum output power to drive the ^{13}C coil described above is 2 kW and 8 kW at 1.5 T and 3.0 T, respectively. 4 kW amplifiers on some 3.0 T systems may be barely adequate.
2nd RF channel or "Stand-alone" decoupler		
^{1}H exciter, ^{1}H amplifier[b]	Proton-decoupling	The decoupling amplifier should be capable of delivering $>$50 W of CW RF power. The output of the amplifier should be high-pass filtered to suppress ^{13}C frequencies.
RF source and modulation capabilities	Generation of a decoupling sequence at the ^{1}H frequency	Typical operating requirements: e.g. WALTZ-4 sequence with a 90 degree pulse range from 0–9.9 ms (in steps of 0.1 ms), bilevel (NOE/decoupling) operation, and manual control of the WALTZ-4 pulse width, attenuation control of output RF power over a 50 dB range in 1 dB steps.
Power meter	Power monitoring	Able to measure forward/reflected RF power. Values (in Watts or dB) should be displayed in real-time, e.g. on a computer screen. In normal operations, hard power limits should force the automatic shutdown of the amplifier if the output exceeds the limits. In addition, it should be possible to establish soft limits that generate warning signals or messages.
Miscellaneous		
Phantom	System/sequence performance evaluation	A spherical phantom containing one or more ^{13}C compounds suitable to test system performance/demonstrate decoupling.

[a] The manufacturers all have specifications for exciter output levels, linearity, phase stability, etc.— the specs for broadband are always a little lower than those for the narrow band imaging exciter.

[b] With amplifiers capable of high CW output, it is advisable that some safety interlock is available to insure that a power limit, e.g. 100 W, cannot be exceeded in normal operation. Typical amplifier specifications: 1000 W (peak)/100 W (CW) into a 50 Ohm load. The RF power amplifier should be electrically connected to the MR scanner so that all automatic, emergency electrical power shutdown procedures apply.

Proton-Decoupler and Power Monitoring

Along with the capability to perform heteronuclear (other than ^{1}H) MRS comes the need to enhance sensitivity and specificity of chemical analyses by *proton-decoupling* and *heteronuclear polarization transfer* and *editing*. This involves excitation at different frequencies, and accordingly requires a second RF channel and amplifier. Since it appears that there is a renewed interest in advanced multinuclear spectroscopy, the major manufacturers of clinical MR scanners are all offering broadband capabilities and second RF channels. There are two basic options for decoupling; a fully integrated, second RF exciter channel

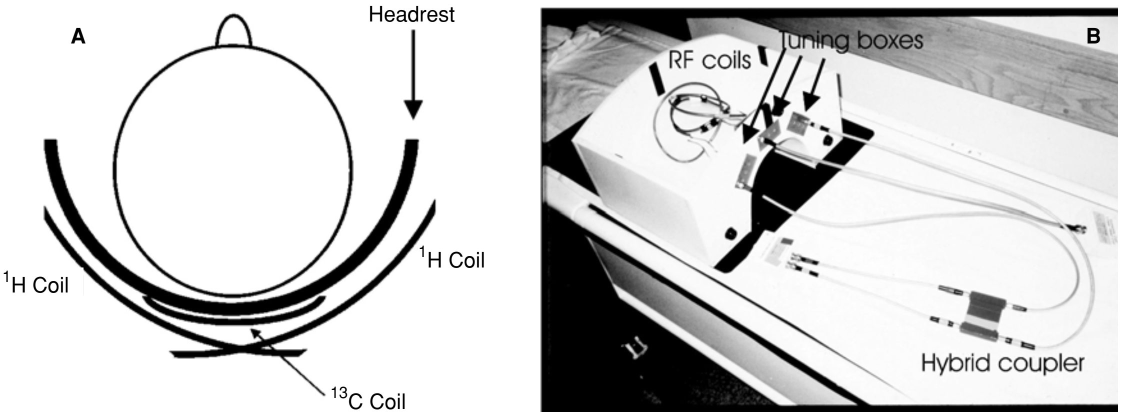

Fig. 1. Dual-tuned RF coil for in vivo ^{13}C MRS of human brain. (**A**) Schematic of the "half-volume" coil assembly as originally proposed by Adriany and Gruetter [2] and since then adopted by other groups. The two orthogonal ^{1}H coils can be used for MRI, ^{1}H MRS, as well as for proton-decoupling during ^{13}C signal reception. A single ^{13}C surface coil is mounted immediately adjacent to the head rest. The overlap of the ^{1}H coils and the position of the individual coils needed to be adjusted to minimize interaction between the different coils. It is also important to minimize the distance between ^{13}C coil and the region of interest to optimize SNR. (B) Picture of the coil assembly used at Huntington Medical Research Institutes, Pasadena, California. A hybrid coupler is necessary to operate the two ^{1}H coils 90° out of phase for quadrature excitation and detection. "Tune and match" is accomplished for each coil individually with three separate tuning boxes. Coils, cables, and connectors are "color-coded" to avoid mistakes when connecting the coil assembly with the MR scanner.

that is part of the MR scanner, or an independent or "Stand-alone" sequence generator with simple timing signals provided by the MR scanner. The fully integrated channel requires pulse sequence programming but gives the user direct access to the decoupling sequence and parameters. Standalone decouplers exist in several flavours, ranging from simple pre-programmed decoupling sequences with hardware control of all parameters to more complex signal generating devices under computer control.

Excessive RF power deposition during decoupling can result in potentially damaging heating of tissue. Federal drug administration (FDA) guidelines limit the deposited energy below levels which are considered to be of any risk [8,9]. Manufacturers have developed decouplers with built-in power monitoring and automatic shutdown should a certain threshold for the average power be exceeded. It should be noted that since for decoupled ^{13}C MRS ^{1}H surface coils are being used, the *local* specific absorption rate (SAR) may vary with the magnetic field profile of the proton coils (B_1). It is possible that the *average* SAR over the whole sensitive volume is below the FDA approved limit, whereas the *local* SAR of tissue adjacent to the ^{1}H decoupling coils may be above that threshold [2,10].

Proton-Decoupling and NOE

Proton-decoupling and the nuclear Overhauser effect (NOE) are essential tools for ^{13}C MRS. It is not advised to attempt ^{13}C MRS without decoupling/NOE. Even the simplest application, such as measuring the lipid profile of a human leg [11], would be quite demanding without the improved SNR and resolution facilitated by decoupling and NOE.

Proton-Decoupling

Heteronuclear scalar couplings between ^{1}H and ^{13}C nuclei result in a splitting of ^{13}C resonance lines in to multiplets. The goal of *proton-decoupling* is to suppress these couplings and to collapse multiplets into singlets, simplifying the spectrum and improving the signal intensity. This is achieved by irradiation of decoupling proton RF pulses during the readout of ^{13}C signal over the whole range of the spectrum (= *broadband* decoupling). The most commonly used proton-decoupling RF sequence for *in vivo* ^{13}C MRS is WALTZ [12–15]. Several WALTZ decoupling schemes have been developed named WALTZ-4, WALTZ-8, and WALTZ-16 and they all appear to work well for *in vivo* applications.

NOE—The NOE is based on changes in the polarization, which occur in coupled systems when the population of one of the systems is manipulated. In contrast to *scalar* coupling, which is facilitated indirectly by the electron bond, it is the *dipolar* coupling between ^{13}C and ^{1}H nuclei, which generates the NOE. In fluids, dipolar coupling does not result in a line splitting due to "Motional Narrowing," however, it is still an effective relaxation mechanism resulting in changes of signal intensities. While it was necessary to irradiate at the proton frequency *during* the readout of ^{13}C signal for proton decoupling, NOE enhancement is generated by irradiation at the proton frequency *before* the ^{13}C signal is detected. Excitation of protons coupled to ^{13}C has an impact on the polarization of ^{13}C. In particular, if the protons are saturated an increase of the polarization of ^{13}C can be observed. Since the maximum NOE enhancement for two nuclei A and B in fluids is given by, $\text{NOE} = 1 + \frac{1}{2}\,\gamma_B/\gamma_A$, a threefold signal enhancement can be achieved for ^{13}C MRS ($\gamma_{1H} \approx 4\gamma_{13C}$). To have maximum NOE enhancement for all resonances it is necessary to irradiate RF over the full chemical shift range of dipolar coupled protons. As for proton decoupling, a WALTZ-*n* cycle can be employed, however, it is usually sufficient to irradiate at a much lower power levels ($\approx$1/10 of decoupling power). The optimum choice for the center frequency and the bandwidth for NOE may be different from what works best for decoupling.

Pulse Sequences for *in vivo* ^{13}C MRS

More detailed discussions of pulse sequences and data acquisition strategies than provided below can be found elsewhere [16,17] and in references therein.

^{13}C Excitation and ^{13}C Detection

Direct detection ^{13}C MRS is the *least sensitive* method and spectra with sufficient quality can only be acquired from very large volumes [18] or without any localization [3]. *Gradient localized* direct ^{13}C MRS is further compromised by considerable chemical shift displacement errors due to the large chemical shift dispersion of ^{13}C spectra. On the other hand, spectra acquired with this method offer high spectral resolution and an impressive number of ^{13}C resonances, all measured simultaneously under identical conditions (Figure 2). In particular when a simple "pulse and acquire" sequence is used, the impact of acquisition parameters on the spectral pattern is small and sequence parameter adjustment is quick. These features may be important in a clinical setting where experimental simplicity is important [19,20]. Direct ^{13}C excitation and detection requires proton-decoupling and NOE to improve the spectral quality.

Polarization Transfer

A better SNR can be achieved with heteronuclear polarization transfer. The basic concept of polarization transfer is to excite protons coupled to ^{13}C and, as the polarization is transferred to the adjacent ^{13}C nucleus during the evolution period, to detect the signal at the ^{13}C frequency. Because the heteronuclear J-coupling constants between ^{1}H and ^{13}C nuclei are very similar ($\approx$120 Hz for methyl groups, $\approx$160 Hz for aromatic groups), sequence parameters, in particular the delay for coupling evolution, can be adjusted to the optimum detection of all signals. There are two distinct features of this method. (i) Proton excitation can be combined with *localization* such as image-selected *in vivo* spectroscopy (ISIS) [21] greatly reducing the chemical shift displacement error [4,22]. (ii) ^{13}C detection retains the large dispersion and thus spectral resolution of ^{13}C (Figure 3). This method also allows recovering the maximum fourfold sensitivity gain due to the higher magnetization of protons. During detection at the ^{13}C frequency, proton decoupling is applied to generate a simplified spectrum for better interpretation. Polarization transfer becomes less advantageous in situations where the resonance of interest has a very short T_2 (e.g. glycogen). If T_2 is short relative to the time delay necessary to facilitate polarization transfer, a substantial loss of signal can occur [17].

Indirect Detection

Indirect detection can improve greatly the sensitivity by detecting protons attached to ^{13}C utilizing heteronuclear scalar couplings. In the simplest case, protons coupled to a ^{13}C nucleus will form two resonances symmetrically placed around the center of the singlet generated by a proton attached to a ^{12}C nucleus. In practice however, the ^{1}H spectra of chemicals such as glutamate and glutamine are complex because of home- and heteronuclear couplings and resonances overlap due to the small chemical shift dispersion of ^{1}H MRS. This renders the detection of ^{13}C coupled protons difficult. It is therefore necessary to apply *editing* pulses at the ^{13}C frequency, which will result in a modulation of a spectrum, e.g. an inversion of the signal from ^{13}C bound protons relative to ^{12}C bound protons. When unedited and edited spectra are analyzed, the difference spectra will represent protons attached to ^{13}C while the added spectrum represents protons bound to ^{12}C. This approach is referred to as *proton-observed, carbon-edited* (POCE) [23]. Indirect detection offers the highest SNR among the methods discussed here and has the advantage of localization at the proton frequency, reducing chemical shift displacement artifacts. Another advantage of indirect detection is that only hardware for the *transmission* of RF at the ^{13}C frequency is required and that the proton channel of MR systems, used for signal detection, is usually well engineered, guaranteeing good performance (Figure 4). A disadvantage is that the high spectral resolution of ^{13}C is sacrificed. While this is acceptable for simple spectra with selective isotopic enrichment, it may

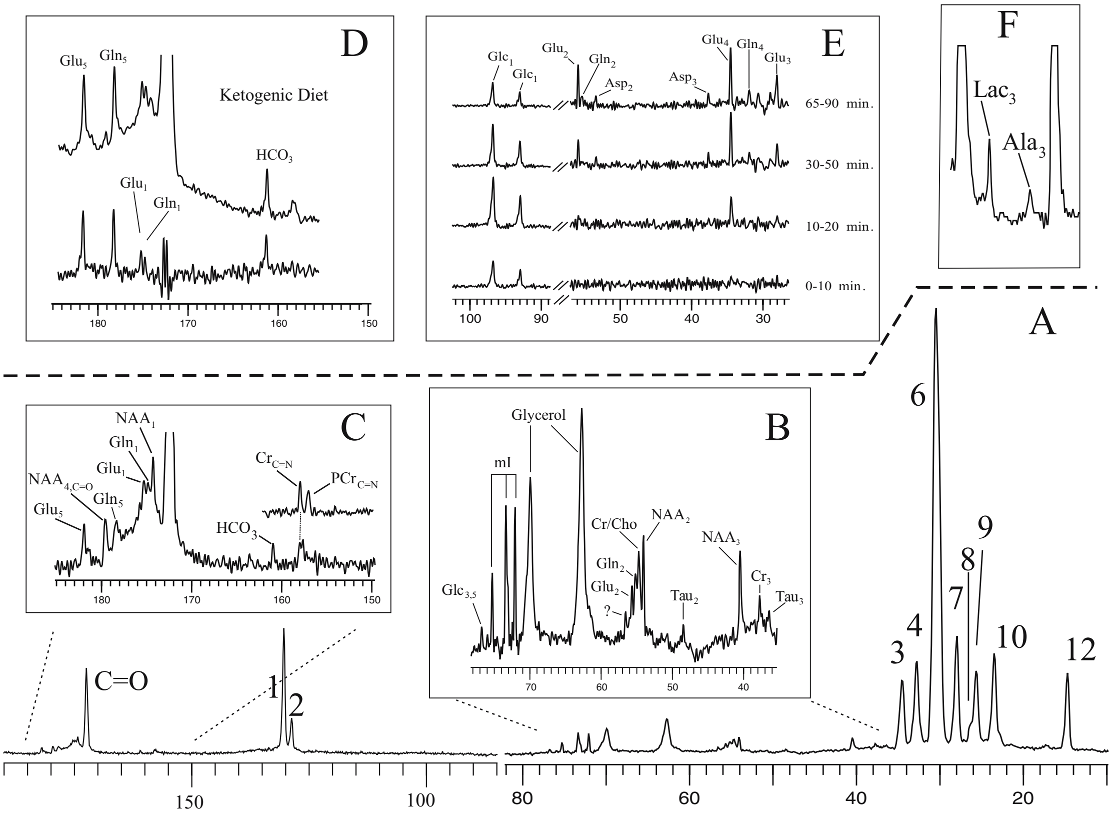

Fig. 2. *In vivo* natural abundance and ^{13}C MR spectra after substrate infusion of the human brain acquired with "pulse-and-acquire" and direct ^{13}C detection. (A–C) Shown is a natural abundance ^{13}C MR spectrum of a patient with Canavan disease. B + C are expansions of A to allow a more detailed inspection. Lipid signal originating from the skull and subcutaneous fat dominates the spectrum due to non-localized acquisition. (D) ^{13}C spectrum (upper trace) obtained from ketogenic diet (KD) patients 30–80 min after infusion [1-^{13}C] acetate. The lower trace is the difference spectrum computed by subtraction of the baseline spectrum, acquired before infusion start, (not shown) to directly illustrates ^{13}C label accumulation. ^{13}C label incorporation into bicarbonate (HCO_3), Glu C_5 and Gln C_5 and, Glu C_1 and Gln C_1 can be observed. (E) The time course of glucose uptake and metabolism to glutamate and other products in the brain in a normal adult subject after i.v. [1-^{13}C] glucose infusion. Difference spectra were calculated to subtract prominent lipid peaks. ^{13}C enriched peaks of Glu $C_{1,2,3,4}$, Gln $C_{1,2,3,4}$, Asp $C_{2,3}$, NAA $C_{2,3}$ can be observed [36]. (F) Although lactate (Lac) and alanine (Ala) concentrations are too low to be detected with natural abundance ^{13}C MRS in normal brain, ^{13}C enriched resonances are readily observed after [1-^{13}C] glucose infusion. All spectra were acquired with the dual-tuned half-volume head coil shown in Figure 1 on a GE, 1.5 T clinical scanner.

be more problematic when high resolution of complex spectra with many components is the goal.

Checking System Performance

Once the required hardware is installed and an MR sequence developed, the next essential step is the thorough evaluation of the system performance.

Low SNR

Low overall SNR of ^{13}C MRS may be caused by several reasons. A poorly designed or tuned ^{13}C coil will not provide adequate SNR. Also, poor SNR may be caused by site specific factors. RF noise at ^{13}C frequency may be generated by other MR equipment used for MRI and not filtered appropriately. Also, equipment not related with MR may emit RF at the frequency of ^{13}C and adversely

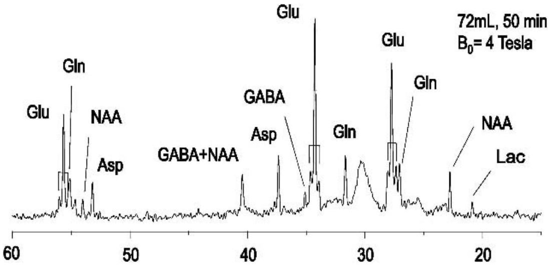

Fig. 3. Localized ^{13}C MR spectrum of the human occipital lobe The spectrum was acquired from 72-ml volume 60–110 min after start of [1-^{13}C] glucose infusion on a 4 T system using polarization transfer, proton excited carbon detected, for improved SNR and localization (Figure provided by Rolf Gruetter, Ph.D. and reproduced with permission from Dev Neurosci 1998 S. Karger AG).

interfere with the quality of a spectrum. There are many tests that can be performed to isolate the cause for insufficient SNR, however, the questions the new investigator faces first are: "How does a good spectrum look like?" "Is the performance of my system the best possible?" For that reason, it is recommended that the investigator should team-up with a reference site with experience with ^{13}C MRS. The coil, a phantom, and specific instruction on how to perform a test should be sent to a collaborating site with the request to acquire data for comparison. Even better, a new investigator may want to visit an established site for ^{13}C MRS to witness a quality scan and to ensure that scans at the reference site and at the local site are performed under identical conditions. Once a problem has been identified or narrowed down, the manufacturer of the MR system or the RF coil can be approached with a specific request to fix a problem.

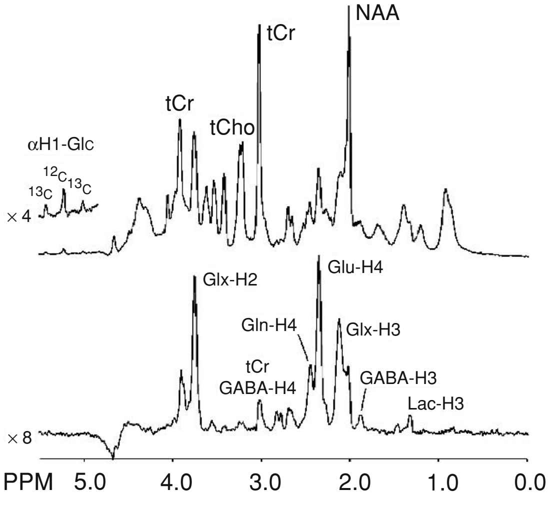

Fig. 4. Indirect detection of ^{13}C label accumulation The spectrum was acquired from rat brain at 9.4 T (180 ul volume, T_R = 4000 ms, T_E = 8.5 ms, 512 averages). It was acquired between 110 and 140 min following the intravenous infusion of [U-^{13}C6]-glucose (i.e. uniformily labelled glucose). The upper trace is the regular ^{1}H spectrum, while the bottom spectrum is the ^{1}H-[^{13}C] edited fraction (i.e. it only shows resonances from protons attached to ^{13}C). The sequence is described in de Graaf *et al.* [37] (figure provided by Robin de Graaf, Ph.D. and reproduced with permission from Wiley-Liss. Inc., 2004).

Crosstalk

Crosstalk between ^{1}H and ^{13}C coils during decoupling is caused by the transmission of RF at the proton frequency with relatively high power while the small ^{13}C signal is received. It can cause two unwanted effects. (i) Although, the ^{1}H signal is suppressed by subsequent filtering, the ^{13}C pre-amplifier usually placed immediately after the ^{13}C coil, sees both ^{13}C and ^{1}H signal. Both signals may be amplified. Since the ^{1}H signal is much larger than the ^{13}C signal it may *saturate* the pre-amplifier. This results in an overall scaling (down) of the decoupled ^{13}C spectrum. It may not affect the SNR but is nevertheless unwanted since an absolute comparison of scans becomes very difficult. (ii) Unacceptable artifacts are caused when decoupling causes spikes at the ^{13}C frequency. Detecting of these two problems is relatively straightforward. If the maximum amplitude of decoupled spectra becomes smaller after further increasing decoupling power, saturation may have occurred. Spikes are readily detectable in the spectrum because of the dramatic adverse impact on the SNR. The problems caused by crosstalk of coils can be minimized by additional filtering of the ^{13}C signal and by using coil assemblies with efficient built-in proton traps. Reducing the decoupling power is useful only when it does not result in incompletely decoupled spectra.

Incomplete Decoupling

Insufficient decoupling power results in a "hybrid" spectrum, partially non-decoupled and partially decoupled. These spectra are not quantifiable and should not be interpreted.

Instabilities

Scanner and coil instabilities are often another concern. Electronic components may heat-up during a pro-longed acquisitions and change the tuning of a coil, an amplifier may not deliver the same power over an extend period of time, etc. Usually these variations are small, however, in particular when difference spectroscopy is attempted or the time course of a signal is observed over a long time, the quality of the results and the accuracy of the interpretation may be compromised. Scanner and coil instabilities can readily be checked in vitro by scanning phantoms.

Reproducibility

The nature of a study defines when insufficient reproducibility (= different results from the same subject on different occasions) is a problem. Hardware imperfections can cause insufficient reproducibility. However, often the positioning of a subject, selection of region of interest, adjustment of acquisition parameters, shimming, etc. is not consistent thus limiting the reproducibility. These problems can be minimized/avoided by generating macros (if possible), dedicated protocols, and clear written instruction on how to conduct a scan. Macros, protocols, and instructions should be tested by scanning different phantoms. Sequence parameters should not be "guessed" when starting an acquisition. Ideally, good and reproducible spectra should be obtained without the need to "manually" adjust scan parameters in each cause. If the lack of reproducibility is small compared with the postulated differences between two groups of subjects, it only complicates the study by the need to examine more individuals in order to reach significance. It is always a good strategy to conduct several studies in the same subject to investigate this matter. There are of course limitations to that when a study is very complex such as a lengthy examination with substrate infusion.

Data Processing

High quality spectra are of no use if the information they contain is not or incorrectly extracted. Therefore appropriate data processing is as important as the acquisition of the spectra. In general, data processing should be as *user independent* as possible to prevent unavoidable operator bias.

Since the signal generated by a specific nucleus is proportional to the number of equivalent nuclei in the volume of interest (VOI), *in vivo* concentrations of a metabolite M (in mmol/kg tissue or mmol/l) can be determined by $[M] = C_{\mathrm{MRS}} A_{\mathrm{M}}$, where C_{MRS} comprises all correction factors (T_1 saturation, T_2 relaxation, VOI, number of equivalent nuclei, receiver gains, etc.) and A_{M} is the total area under a curve. Resonances in decoupled ^{13}C spectra are usually well resolved and line fitting of individual resonances is relatively straightforward. However, when quantifying spectra of low SNR (^{13}C spectra are compromised by low SNR), the investigator may want to keep in mind that not all parameters of a curve are measured with the same accuracy. In particular the determination of the position of a resonance on the chemical shift axis and the amplitude can be measured with a much higher accuracy than the width (or area). Therefore, most of the time, it is advantageous to measure peak amplitudes instead of areas. On the other hand, the amplitude is affected by the homogeneity whereas the area is not. Nevertheless, in a well-designed study, spectra are acquired from comparable regions of interest and the variation of the homogeneity across subjects should be very small and there should be no correction necessary. In cases where small systematic variations could be expected (e.g. when a comparison of spectra from different brain region is attempted), it is still better to perform an adjustable lineshape correction (see below) and to measure amplitudes rather than areas. If due to the nature of a study, large systematic differences of the field homogeneity is expected then areas rather than amplitudes should be evaluated.

Lineshape Transformation

For spectra of low SNR and partially overlapping peaks it is generally advisable to perform a lineshape transformation. A common lineshape transformation is the Lorentzian-to-Gaussian transformation. The first step is a negative Lorentzian linebroadening to create a spectrum with a standardized linewidth. E.g. a spectrum with resonances with 4 Hz linewidth will be corrected by −3 Hz whereas a spectrum with resonances with 4.5 Hz linewidth will be corrected by −3.5 Hz to result in standardized spectra with a 1 Hz linewidth. The second step is a positive Gaussian linebroadening to improve SNR. Although this lineshape transformation is not linear (= the relative areas of peaks with different linewidths are not the same after transformation), in practice, this imperfection is more than compensated for by the fact that Gaussian lines can be fitted much easier than Lorentzian lines because of the reduced overlap of adjacent resonances.

LCModel for ^{1}H MRS

^{13}C spectra are usually well resolved and fitting of the individual resonances can be achieved relatively straightforward. Should the user decide to use inverse detection, proton spectra need to be processed. Proton spectra suffer from the narrow chemical shift range, complex pattern due to homonuclear couplings, and a broad baseline due to macromolecules. On the other hand, good processing software for ^{1}H MRS is commercially available. LCModel (Linear combination of model spectra, Stephen Provencher Inc., Oakville, Ontario, Canada) is a well-developed, robust, and at the same time flexible software package [24]. LCModel fits the *in vivo* data by finding the best linear combination of spectra obtained from phantoms with known concentrations. LCModel is most suited for standard ^{1}H MRS as carried out in a clinical environment (e.g. 1.5 T, 2.0 T, 3.0 T, PRESS, STEAM) with pre-measured basis spectra available from the vendor. For applications with complex acquisition sequences and unusual sequence parameters the user may need to prepare his/her own phantoms to acquire the appropriate model spectra the specific experimental conditions. Although this can be tedious when many metabolites are being analyzed, it is time well spent.

Modeling and Determination of Flux Rates

Infusion of a ^{13}C labeled substrate allows the metabolism of the substrate to be followed by sequential ^{13}C MRS. A *mathematical model*, basically a set of differential equations, of the metabolism is then needed to determine the *in vivo* flux rates (Figure 5). It needs to be pointed out that the formulation of the differential equations for a biological model is the easy part—finding the right model is the tricky part. Assumptions and simplifications are necessary, even if the correct model is known [e.g. for the tricarboxylic acid (TCA) cycle] because only a limited number of metabolites can be measured with sufficient SNR. E.g. the measurement of the TCA-cycle rate after [1-^{13}C] labeled glucose infusion is based to a large extent on the time course of the glutamate C_4 enrichment. However, glutamate is NOT a metabolite of the TCA-cycle. Only because the pool sizes of TCA-cycle intermediates are small and the exchange rate between α-ketoglutarate and glutamate is fast (there are some controversies in the literature on how fast "fast" is), it is reasonable to assume that glutamate C_4 acts as a trap for ^{13}C label entering

Flux Rates

Fig. 5. (A) Dynamic ^{13}C MRS involves the sequential acquisition of ^{13}C spectra after substrate infusion to ^{13}C label accumulation. (B) The next step is the processing and quantitation of spectra to generate time courses of ^{13}C concentration (or ^{13}C enrichment). (C + D) A set of differential equations is derived from the metabolic model applied for an experiment. (E) By iteratively varying flux parameters (and pool concentrations) of the mathematical model to optimize the fit with experimental data, flux rates (and pool concentrations) can be determined.

the TCA-cycle at acetyl-Coa [25]. It is beyond the scope of this chapter to get involved in the discussion of current complex models of glucose and acetate metabolism in animal and human brain and it is recommended that the interested reader studies recently published articles [1]. Sometimes it is possible to simplify the mathematical model considerably to answer very specific questions. Examples are the determination of the N-acetyl-asparate synthesis rate in humans *in vivo*, the glutamine synthesis rate in human hepatic encephalopathy, or the measurement of the astro-glial TCA-cycle rate after [1-^{13}C] acetate infusion [20,26,27].

A simple two Compartment Model—Mathematical Description

$$S_0 \xrightarrow{V_1} S_1 \xrightarrow{V_2} S_2$$

In this model S_0 is the initial substrate and S_1, S_2 are intermediates of S_0 metabolism. $[^{13}S_0]$, $[^{13}S_1]$, $[^{13}S_2]$ are the ^{13}C enriched pools; e.g. before infusion $[^{13}S_1] = 1.1\%$ $[S_1]$. V_1 and V_2 are the fluxes from S_0 to S_1 and from S_1 to S_2. Assuming that the total concentration of S_1 remains constant ($V_1 = V_2$), the ^{13}C flux into and out of pool S_1 is described by:

$$\frac{d}{dt}[^{13}S_1] = \frac{[^{13}S_0]}{[S_0]}V_1 - \frac{[^{13}S_1]}{[S_1]}V_2. \qquad (1)$$

In the special case that the fractional enrichment of substrate S_0 is constant ($[^{13}S_0]/[S_0] = E_0 =$ constant), the ^{13}C enrichment of S_1 will exponentially approach that of the precursor:

$$[^{13}S_1](t) = E_0[S_1] \times \left(1 - \exp V_1 t \big/ [S_1]\right) \qquad (2)$$

Since the time constant for the pool to turn over is the ratio of pool size and flux rate ($[S_1]/V_1$), large metabolic pools take longer to turn over whereas small pools will quickly have the same enrichment as the precursor. For this hypothetical model, the concentration of ^{13}C enriched S_1, would be measured by sequential MRS. Once the total pool size is known (e.g. from literature, quantitative natural abundance ^{13}C, or ^{1}H MRS), the flux rate V_1 can be obtained by fitting an exponential function to the measured time course for $[^{13}S_1]$.

Real biological systems, although analytical differential equations for each metabolic pool can be written readily, are too complex for analytical solutions and numerical solutions need to be found by a step-by-step integration. Software (CWave, Graeme Mason, Ph.D., Yale University) for the design of models and analysis of ^{13}C-labeling studies is available after signing a license agreement [28]. To obtain a copy contact Graeme Mason, Ph.D., at the Magnetic Resonance Center, Yale University, School of Medicine.

Miscellaneous

Even when all technical obstacles have been resolved, the investigator still needs to plan any study very carefully. *In vivo* ^{13}C studies, in particular of human requiring large amounts of ^{13}C labeled substrates, are expensive, lengthy, and the subsequent data analysis requires a considerable effort. To avoid frustration and jeopardizing the success of a ^{13}C experiment, all "peripheral" steps of a study need to be planned with equal due diligence than the acquisition of the ^{13}C spectra. Depending on the biological question asked, it needs to be decided what substrate should be infused for how long and in what fashion. For some applications oral administration may be appropriate [29,30,26] which would simplify the procedure considerably because one inter-venous (i.v.) infusion line could be eliminated. In particular for studies of humans, i.v. administered substrates should be prepared with care, kept refrigerated, and used within a couple of days. It is usually necessary to determine fractional ^{13}C enrichment of the substrate in plasma. Therefore the drawing, storage, and analysis of blood samples need to be planned. A new investigator is advised to carefully read the "Methods" sections of previous publications [22,25,28] and references therein.

Applications

Although there are undoubtedly applications for *in vivo* natural abundance ^{13}C MRS, to harvest the full potential of ^{13}C MRS, enrichment of metabolites with ^{13}C via intravenous or oral administration of ^{13}C labeled substrates is necessary. Glucose is the principal substrate for energy metabolism for both neurons and glia cells in the brain and also facilitates the *de novo* synthesis of many neurochemicals. In normal human adults, i.v. infused [1-^{13}C] labeled glucose (Glc) passes the blood-brain barrier and is readily metabolized. ^{13}C enrichment of individual carbon atoms of glutamate (Glu), glutamine (Gln), aspartate (Asp), N-acetylaspartate (NAA), γ-amino butyric acid (GABA), lactate (Lac), alanine (Ala), and bicarbonate (HCO_3^-) follows [5,19,20,22,25,31]. From repeated ^{13}C MR spectra acquired during studies over 2–3 h, the *in vivo* rates of several of the principal bioenergetic pathways of normal adult brain have been determined [22,25,4].

The role of ^{13}C glucose MRS in *diseased brain* remains a matter of speculation as there are only a few studies

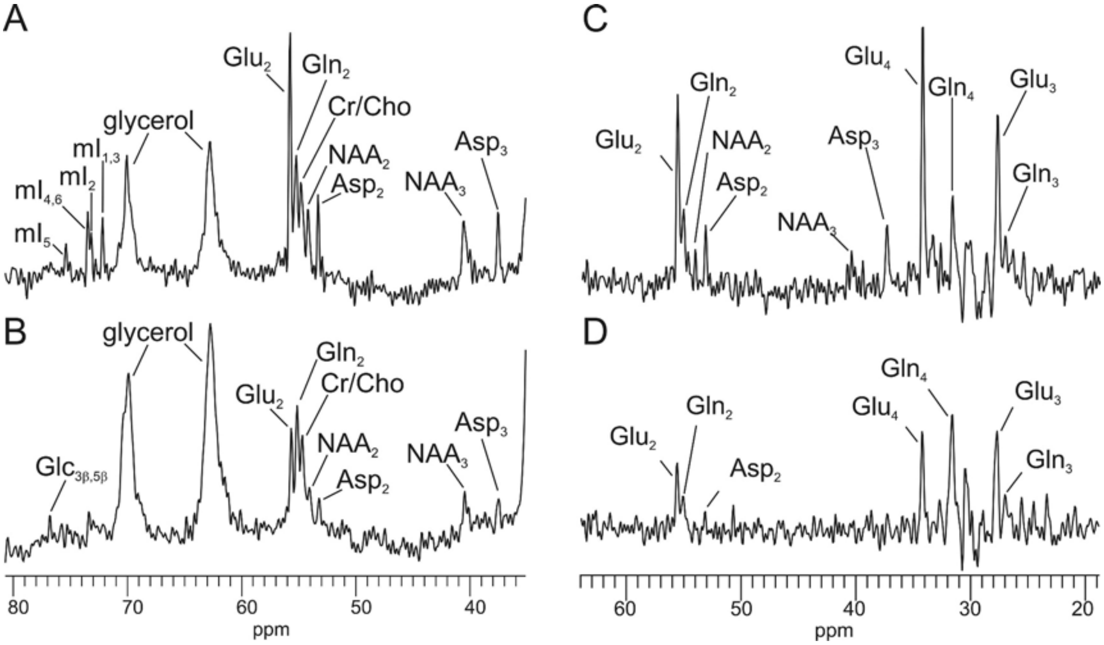

Fig. 6. ^{13}C MRS of human hepatic encephalopathy (HE) Hepatic encephalopathy is a metabolic brain disorder caused by liver dysfunction and incomplete removal of ammonia and other neurotoxins from the blood. (**A+B**) Spectra acquired over a period of 60–120 min after a 20 min infusion of $[1-^{13}C]$ glucose of an adult control (A) and a patient with severe chronic HE (grade III–IV) are shown. ^{13}C enrichment of Glu C_2, Asp C_2, Asp C_3 is reduced while ^{13}C accumulation in Gln C_2 is comparable to the control. Note the absence of natural abundance *myo*-inositol (mI) signal in HE. (**C+D**) Difference spectra, to enable inspection of ^{13}C accumulation in Glu C_4, Gln C_4, Glu C_4, and Gln C_4, of a control and a chronic HE patient (grade I-II) acquired 80–100 min after infusion start, are shown. Spectra were scaled to represent absolute concentrations. Note the apparent reduction of ^{13}C incorporation into Glu C_4, C_2, Asp C_2,3 in HE. Even though affected by the subtraction analysis to a larger extent in HE than in control, the Gln C_4 resonance appears strikingly prominent in spectra of the patient. Label accumulation in NAA C_2,3 observed in the control was not detected in HE. The pattern of label accumulation in HE is consistent with an overall reduction of glucose oxidation and altered glutamate/glutamine cycling.

conducted. Striking abnormalities in glucose metabolism and glutamate and glutamine label accumulation were observed in patients with chronic hepatic encephalopathy (Figure 6). Glucose oxidation was also reduced in a juvenile with hypoxic injury and in a premature infant. Abnormalities were also detected in pediatric patients with leukodystrophies and in children with mitochondrial disorders [19,20]. The information obtained from following the fate of ^{13}C labeled glucose goes beyond that of providing a rate for energy production. A tight coupling between cerebral glucose metabolism and glutamate neurotransmitter flux in humans has been proposed by Magistretti *et al.* [32]. Aspartate, (a neurotransmitter?), can be studied *in vivo* in humans by its ^{13}C label accumulation. The role of NAA in mammalian brain, a neuronal/axonal marker which is central for its diagnostic power in ^{1}H MRS, is incompletely understood. NAA synthesis can be measured with ^{13}C MRS after glucose infusion in a clinical setting [26] (Figure 7).

The application of ^{13}C MRS after substrate infusion is by no means limited to glucose. Glucose is convenient because of its rapid oxidation and the fast appearance of ^{13}C label in its metabolites and its non-toxicity even at extremely high concentrations. However, the use of other substrates may further enhance the potential of ^{13}C MRS as a research and diagnostic tool in human brain disease. The candidate next best to glucose appears to be acetate [7,27]. Acetate (Ac) is metabolized to acetyl-CoA only in the glial compartment [33]. Using the same MR technique as for $[1-^{13}C]$ glucose, glial acetate metabolism can be investigated in normal and diseased brain. ^{13}C label accumulation in HCO_3, in Glu C_5 and Gln C_5 (first turn of the TCA-cycle), and in Glu C_1 and Gln C_1 (second turn) can be observed after $[1-^{13}C]$ Ac in fusion. Fig. 7. Determination of N-acetyl-aspartate synthesis rate, V_{NAA}, in humans *in vivo* (A) ^{13}C labeling scheme used to predict the transfer of ^{13}C label from Glu$_4$ to Asp$_{2,3}$. Only relevant TCA-cycle intermediates are shown (B). N-acetyl-aspartate (NAA) synthesis by condensation of aspartate and Acetyl CoA. (C) Human brain natural abundance (baseline) and ^{13}C enriched spectra after [1-^{13}C] glucose infusion. The time intervals indicate the time of acquisition relative to the commencement of [1-^{13}C] glucose infusion. Peak intensities of Asp$_2$ and NAA$_2$ (as well as Glu C$_2$ and Gln C$_2$) increased progressively as ^{13}C label accumulates. (D) Fractional ^{13}C enrichment of NAA (E_{NAA2}) versus time was lower in patients with aspartoacylase deficiency (Canavan Disease) than in control subjects. Linear regression lines are superimposed on data points $t > 50$ min in each group. The calculated mean rate of *in vivo* NAA synthesis in normal subjects was 9.2 ± 3.9 nmol/min/g. In patients with Canavan Disease statistically significant reductions of [Asp] and [Glu] were observed. NAA pool size was increased and V_{NAA} was significantly lower (3.6 ± 0.1 nmol/min/g, $p < 0.001$) than in controls. V_{TCA} = TCA-cycle rate, V_{x} = α-ketoglutarate/glutamate exchange rate. V_{gln} = glutamine synthesis rate, V_{xa} = oxaloacetate/aspartate exchange rate, Cit = citrate, Suc = succinate, Pyr = pyruvate, AcCoA = Acetyl CoA.

oxidation in human brain was estimated to be ≈20% of the total neuronal/glial TCA-cycle rate in fasted human brain [7,27]. Recently it was demonstrated that Glu C_5 and Gln C_5, which are primarily derived from acetate in the glial compartment, accumulated more in patients on ketogenic diet (KD) than in controls, whilst accumulation of bicarbonate was similar [34] (Figure 8). These results are consistent with altered glutamate-glutamine neutrotransmitter cycling and adaptation to ketogenic diet with up-regulation of acetate oxidation relative to glucose oxidation. KD is a treatment option for epileptic patients, which is particularly effective in children. The biochemical mechanisms why KD improves seizure activity are incompletely understood. *In vivo* ^{13}C MRS may elucidate a possibly biochemical basis for reduction in seizures during KD therapy. These studies indicate that ^{13}C MRS is an appropriate tool to investigate diseases which are believed to originate in glial cells. Together with data from glucose infusion experiments this could result in a more complete understanding of cerebral metabolism in normal and diseased human brain.

Hyperpolarized ^{13}C Compounds

Recently, dynamic nuclear polarization was used to obtain highly polarized ^{13}C nuclei in endogenous substances such as isotopically enriched ^{13}C urea [35]. Methods have been developed to perform the polarization process outside the body and a nuclear polarization of 50% for ^{13}C appears to be possible [35]. This polarization corresponds with an enhancement of 500,000 (!) compared with the thermal equilibrium polarization at 1.5 T for ^{13}C. Hyperpolarization vanishes due to longitudinal relaxation (T_1) and spectroscopy studies with the goal to investigate metabolic pathways face two major obstacles. (i) The hyperpolarized substrate needs to reach the organ of interest quickly and (ii) turnover rates need to be sufficiently fast to allow the observation of metabolites of a hyperpolarized substrate. Therefore, the application of hyperpolarized substrates to study normal and abnormal metabolism depends mainly on the capability to prepare metabolically active, non-toxic substrates with long T_1-times. Once that is achieved, the promise of ^{13}C MRS with endogenous substances is enormous. Already, Golman *et al.* [35] report a T_1-time of 20 s for ^{13}C urea *in vivo*. The polarization of such a substrate would still be ≈10 times higher than the thermal equilibrium polarization 4 min after injection. A hyperpolarized compound with a T_1 of 40 s would have a ≈1000 (!) higher polarization and a hypothetical 12 day acquisition time could be shortened to 1 s without compromising SNR! As these compounds become available, detailed studies of chemicals of low concentrations in tissue, first in animals and then in humans, may be feasible. In particular, the study of neurotransmitters, until now out of reach for spectroscopist may become a reality.

Glossary

Absolute quantitation—Determination of concentrations of metabolites in mMoles per kg of tissue or volume.

***B*₀**—Strong magnetic field, constant in time and space, generated by the superconducting magnet.

***B*₁**—Radiofrequency (RF) magnetic field generated by *radiofrequency coils*.

Hetero-nuclear J-coupling—*J-coupling* between different species of spins, e.g. proton and carbon.

Homo-nuclear J-coupling—*J-coupling* between the same species of spins, e.g. proton and proton.

ISIS—**I**mage-**s**elected *in vivo* **s**pectroscopy is based on a cycle of eight acquisitions which need to be added and subtracted in the right order to get a single volume. ISIS is considerably more susceptible to motion then *STEAM* or *PRESS* and is mostly used in heteronuclear studies, where its advantage of avoiding T_2*-relaxation* is valuable.

J-coupling (or scalar coupling)—Many resonances split into multiplet components. This is the result of an internal indirect interaction of two spins via the intervening electron structure of the molecule. The coupling strength is measured in Hertz (Hz) rather than *ppm* because it is independent of the external B_0 field strength.

NOE—Nuclear Overhauser effect, the magnetization of protons dipolar-coupled to ^{13}C nuclei can be used to enhance the ^{13}C signal. While the term NOE is mainly associated with ^{13}C MRS, NOE enhancement can also be observed in ^{31}P MRS and with other nuclei.

Polarization transfer—Many interesting nuclei like ^{13}C suffer from low inherent sensitivity compared with proton MR. Techniques like DEPT (**d**istortionless **e**nhancement by **p**olarization **t**ransfer) and INEPT (**i**nsensitive **n**uclei **e**nhanced by **p**olarization **t**ransfer) improve the ^{13}C sensitivity by transferring the higher polarization of coupled protons to the carbon nuclei. Special hardware with two RF channels is needed for polarization transfer experiments. A modification of DEPT and INEPT is reverse DEPT and inverse INEPT where the polarization is transfered back to utilize the higher sensitivity of the protons for observation (inverse detection).

PRESS—Point-resolved spectroscopy, utilizes three 180° slice selective pulses along each of the spatial directions

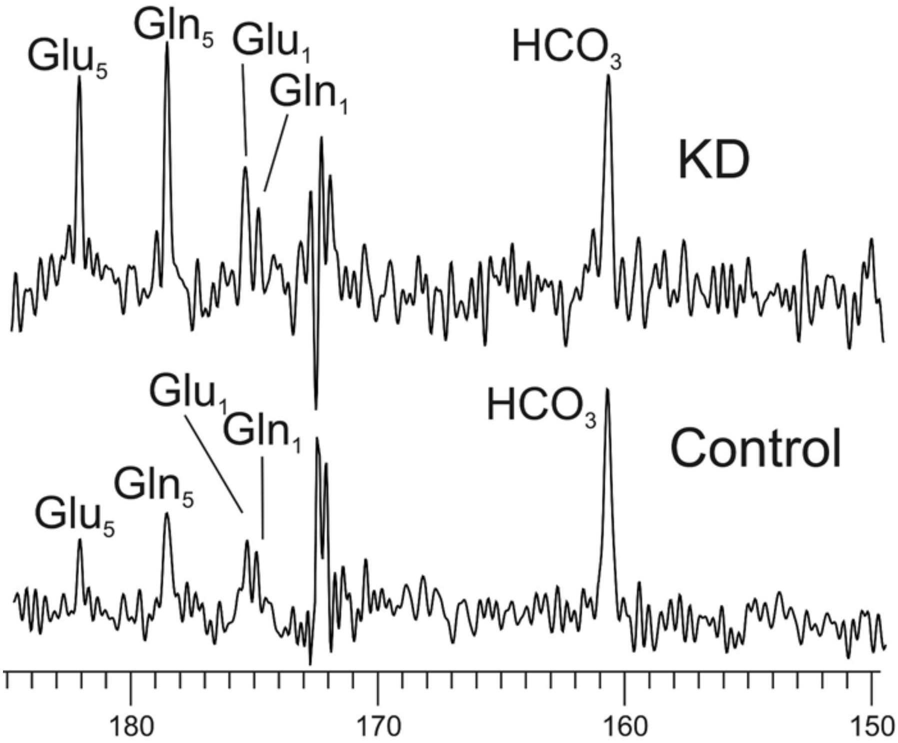

Fig. 8. Impact of ketogenic diet (KD) on astroglial acetate oxidation (A) ^{13}C difference spectra obtained from ketogenic diet patients (average of three) and (B) controls after infusion of [1-^{13}C] acetate. ^{13}C label incorporation into Glu C_5 and Gln C_5 was more pronounced in patients. In addition, Glu C_1 and Gln C_1 enrichment was more prominent, whereas equivalent production of HCO_3 was observed.

and generates signals from the overlap in form of a spinecho.

SAR—Specific absorption rate. Due to inductive and dielectric losses energy from radiofrequency pulses is absorbed by tissue and mainly transferred into rotational and translational movements of water molecules which causes an increase of tissue temperature. Limits for the human brain are established by FDA guidelines.

Scalar coupling—See *J-coupling*

STEAM—Stimulated **e**cho **a**cquisition **m**ode, localization method utilizing three 90° slice selective pulses, along each of the spatial directions. Signal, in form of a *stimulated echo*, from the overlap is generated in a “single shot” experiment. In contrast to *PRESS*, only half of the possible signal is recovered when the same *echo time* is used.

T_1-relaxation, T_1-relaxation time—After the *magnetization* vector has been flipped into the transverse plane, new magnetization builds up along the z-axis. The time after 63% (1-1/e) of the equilibrium magnetization has built up is called the T_1-relaxation time. T_1 and T_2 relaxation is caused by time-dependent fluctuations of local magnetic fields arising mostly from the motion of molecules with electric or magnetic dipoles at the site of the spins. For accurate *absolute quantitation* the relaxation times of all metabolites must be known in order to correct peak intensities appropriately.

T_1-saturation—The repetition times T_R are usually in the range of the T_1*-relaxation* times. As a consequence of this, not all the *magnetization* has recovered, for example when $T_R = T_1$ only 63% of the equilibrium magnetization can be used for each scan (with the exception of the first scan) when 90° flip angles are used for excitation. This effect is called T_1-saturation. The extreme case of saturation occurs when several *RF pulses* are applied within a very short time followed by dephasing *gradients*. This technique is used in localized ^{1}H MRS to remove the dominant water signal (see *water suppression*).

T_2-relaxation, T_2-relaxation time—The *magnetization* vector can be flipped into the transverse plane by using an *RF pulse*. The so generated transverse magnetization undergoes an exponential decay. The time after the magnetization has relaxed to 37% (1/e) of its amplitude is called the T_2 or transverse or spin-spin relaxation time. See also T_1- *relaxation*.

T_R (repetition time)—The time between each initial excitation of the magnetization is called the repetition time.

Magnetic Resonance Spectroscopy and Spectroscopic Imaging of the Prostate, Breast, and Liver

Mark G. Swanson, Susan M. Noworolski, and John Kurhanewicz
Center for Molecular and Functional Imaging, Department of Radiology, University of California, San Francisco, CA 94107, USA

Metabolite Abbreviations: Ala, Alanine; ATP, Adenosine triphosphate; Cho, Choline; Cr, Creatine; Eth, Ethanolamine; Glx, Glutamine/Glutamate; GPC, Glycerophosphocholine; GPE, Glycerophosphoethanolamine; Lac, Lactate; MI, *myo*-Inositol; NAA, N-acetyl aspartate; NTP, Nucleotide triphosphate (e.g. ATP); PC, Phosphocholine; PCr, Phosphocreatine; PE, Phosphoethanolamine; Pi, Inorganic phosphate; SI, *scyllo*-Inositol; Tau, Taurine; UDP, Uridine diphosphate.

Introduction

In this chapter, we describe the current and potential role of magnetic resonance spectroscopy (MRS) and magnetic resonance spectroscopic imaging (MRSI) in organs of the body with an emphasis on the technical aspects of applications in prostate and breast cancer, and diseases of the liver. In contrast to anatomical magnetic resonance imaging (MRI), which detects changes in the relaxivity or density of bulk tissue water, spectroscopy detects small molecular weight metabolites within the cytosol of cells or within extracellular spaces such as glands or ducts. The addition of spectroscopy has been shown to improve the ability (i.e. sensitivity, specificity, and accuracy [1]) of conventional MRI to detect and stage prostate and breast cancer [2–4] and has shown promise in the evaluation of primary and metastatic liver tumors [5] and other liver diseases [6,7]. However, the potential of spectroscopy is even greater because multiple metabolic markers may be combined to provide an independent assessment of disease state, cancer aggressiveness, and therapeutic response [8–10]. The clinical use of spectroscopy as an adjunct to MRI has expanded dramatically over the past several years. This has been due to both the need to answer clinically relevant questions and recent technical advances in hardware and software that have provided improvements in the spatial and time resolution of the spectral data and have resulted in the incorporation of this technology on commercial MR scanners. These breakthroughs have allowed the routine addition of spectroscopy sequences to clinical MRI exams, and have led to spectroscopy being factored into the clinical decision process.

Historically, ^{31}P and ^{1}H have been the nuclei of choice for *in vivo* MRS in the body and each has distinct advantages and disadvantages. The major advantage of ^{1}H spectroscopy is its high sensitivity, which is necessary to achieve high spatial resolution (< 1 cm^3) in a clinically reasonable amount of time. Because the sensitivity of ^{31}P is only 6.6% that of ^{1}H, much larger voxel sizes (typically >8 cm^3) must be used to achieve the same sensitivity in the same amount of time. ^{31}P MRS also suffers from long T_1 and short T_2 relaxation times relative to ^{1}H. The inherently low sensitivity of ^{31}P MRS can be improved by broadband ^{1}H decoupling (e.g. WALTZ) during the acquisition, which sharpens signals by collapsing multiplets and produces a large nuclear overhauser enhancement (NOE) [11], and through the use of higher magnetic field clinical MR scanners. The major advantages of ^{31}P MRS are that no water or lipid suppression is needed and there is less spectral overlap because a relatively small number of metabolites are dispersed over a large spectral window ($\sim$25 ppm[1]). However, both ^{1}H and ^{31}P spectroscopy require additional hardware, software, and post-processing and display tools, much of which can now be purchased in the form of spectroscopy packages from the major MR manufacturers General Electric, Siemens, and Philips.

Several metabolites are present in high enough concentrations (>1 mM) to be detected by ^{1}H or ^{31}P MRS, although many have not yet been detected or fully exploited *in vivo* in the body. The ^{1}H MR spectrum spans a frequency range of about 10 ppm and is centered around water at 4.8 ppm. To date, the resonances

---

[1] Parts-per-million (ppm) is a dimensionless unit used to describe differences (usually from zero) in chemical shift (δ) independent of the applied frequency (B_0). Frequencies in Hertz (Hz) are converted to ppm by dividing the value by the carrier frequency in MHz and multiplying by 10^6. For example, a magnetic field strength of 1.5 T corresponds to a ^{1}H carrier frequency of $\sim$63 MHz, such that 1 ppm $\approx$ 63 Hz, whereas at 3.0 T, 1 ppm $\approx$ 126 Hz.

Graham A. Webb (ed.), Modern Magnetic Resonance, 1113–1125.
© 2008 *Springer.*

upfield of water have received the most attention, including lactate (Lac, $\delta = 1.33$ and 4.12 ppm), alanine (Ala, $\delta = 1.48$ and 3.78 ppm), glutamine/glutamate (Glx, $\delta = 2.04, 2.11, 2.35$, and 3.76 ppm), taurine (Tau, $\delta = 3.26$ and 3.43 ppm), *myo*-inositol (mI, $\delta = 3.28, 3.54, 3.60$, and 4.05 ppm), *scyllo*-inositol (sI, $\delta = 3.35$ ppm), creatine/phosphocreatine (Cr/PCr, $\delta = 3.04$ and 3.93 ppm), the choline containing compounds choline (Cho, $\delta = 3.21, 3.55$, and 4.07 ppm), phosphocholine (PC, $\delta = 3.23$, 3.62, and 4.18 ppm) and glycerophosphocholine (GPC, $\delta = 3.24, 3.68$, and 4.34 ppm), and the ethanolamine containing compounds ethanolamine (Eth, $\delta = 3.15$ and 3.80 ppm), phosphoethanolamine (PE, $\delta = 3.22$ and 3.99 ppm), and glycerophosphoethanolamine (GPE, $\delta = 3.30$ and 4.12 ppm). Healthy prostate tissue is unique in that citrate ($\delta = 2.55$ and 2.71 ppm) [12] and polyamines (predominantly spermine, $\delta = 3.11, 2.09$, and 1.78 ppm) [13] are also present in very high concentrations and can be readily observed by ^{1}H MRS. There is also much interest in observing glucose (3.43, 3.80, and 5.23 ppm) and uridine diphosphate (UDP) sugars (5.5–6.1 ppm), which resonate very close to water, because of the role of increased glycolysis in cancer [14]. It has also been demonstrated that amide proton transfer from the downfield exchangeable amide protons of proteins and peptides ($\sim 7.8-8.8$ ppm) to water can improve sensitivity by several orders of magnitude and provide a novel imaging mechanism [15].

The major contributors to the ^{31}P MR spectrum include inorganic phosphate (Pi, $\delta = 2.26$ ppm), phosphocreatine (PCr, $\delta = -2.89$ ppm), the phosphomonoesters (PC and PE, $\delta = 3.76$), the phosphodiesters (GPC and GPE, $\delta = 0.11$ and 0.74 ppm), diphosphodiesters (e.g. UDP sugars, $\delta = -11.07$ and -12.76 ppm), and nucleotide phosphates [e.g. adenosine triphosphate (ATP), $\delta = -5.24, -10.37$, and -19.02 ppm] [16]. ^{31}P chemical shifts are typically referenced to either *in vivo* PCr or external 85% H_3PO_4 (as listed here). It should be noted that when ^{31}P chemical shifts are reported with PCr set to 0.00 ppm, the values are 2.89 ppm greater than the corresponding values referenced with H_3PO_4 set to 0.00 ppm. It is also widely believed that ^{13}C spectroscopy, which to date has been primarily limited to the brain [17,18], will play a major role in the future of body MRS as higher field human scanners, ^{13}C labeled substrates (e.g. glucose, acetate, and pyruvate), and commercial ^{13}C hyperpolarizers [19] become more widely available and approved for human studies. However, because ^{13}C MRS is described elsewhere in this book, it will not be further discussed in this chapter.

Previous MR studies on prostate, breast, and liver tumors have identified elevated levels of phosphomonoesters and phosphodiesters (detected by ^{31}P MRS) [5,16,20–24] and elevated levels of the composite Cho resonance (detected by ^{1}H MRS) relative to normal healthy tissues [4,12,20,25–29]. Although the *in vivo* ^{1}H signal that is attributed to Cho contains contributions from Cho, PC, GPC, Eth, PE, GPE, Tau, *m*I, and *s*I, the Cho head group contains nine equivalent protons; consequently, a small increase in concentration results in a large increase in signal intensity. In cancer, the observed increases in Cho and Eth containing compounds have been primarily associated with increased cell membrane synthesis and degradation [24]. However, changes in cell density and altered phospholipid metabolism with cancer evolution and progression also contribute to the observed changes in phospholipid metabolites [27,30].

In spectroscopy it is also very important to identify markers for healthy or normal tissue that can be used for quantitation purposes. In ^{31}P MRS, metabolite ratios are often calculated relative to Pi, PCr, or NTP. In studies of cancer, before and after therapy, the phosphomonoester to phosphodiester ratio is particularly useful because it compares markers of proliferation (PC and PE) to markers of cellular breakdown or apoptosis (GPC and GPE). ^{1}H MRS has been highly successful in the prostate and brain because, in addition to increased Cho, there are unique markers for healthy tissue that decrease in cancer [31]. Consequently, the ratios of Cho to citrate in the prostate and Cho to N-acetyl aspartate (NAA) in the brain are significantly greater in regions of cancer compared to surrounding healthy tissues [2,32]. However, because citrate and NAA are not observed in any other tissues of the body, novel markers for healthy tissue, which may or may not change with malignancy or disease, are needed.

Techniques for Spectroscopy and Spectroscopic Imaging of the Body

Spatial Localization

The most common localization schemes for single voxel spectroscopy are image selected *in vivo* spectroscopy (ISIS) [33], stimulated echo acquisition mode (STEAM) [34], and point resolved spectroscopy (PRESS) [35]. ISIS consists of a series of selective inversion (i.e. 180°) pulses, which are turned on and off according to an eight-step encoding scheme, in the presence of magnetic field gradients. Because the magnetization remains along the "z" axis prior to the read pulse, ISIS is relatively insensitive to T_2 relaxation, and therefore has historically been popular for ^{31}P MRS. However, ISIS is particularly sensitive to motion because the eight transients must be added and subtracted to achieve spatial localization. Consequently, STEAM and PRESS, which are capable of three-dimensional (3D) localization in a single acquisition, are preferred for ^{1}H MRS studies in the body.

The STEAM radio frequency (rf) pulse sequence can be represented as $90^\circ - t_1 - 90^\circ - t_2 - 90^\circ - t_1-$ acquire, where t_1 and t_2 are inter-pulse delay times. STEAM generates three FIDs, four spin echoes, and one "stimulated echo" at distinct temporal positions, depending on t_1 and t_2, and the unwanted coherences are removed by applying crusher gradients. The desired stimulated echo appears at time $2 \times t_1 + t_2$ and corresponds to the signal from the volume of interest. The PRESS rf pulse sequence can be represented as $90^\circ - t_1 - 180^\circ - t_1 - t_2 - 180^\circ - t_2-$ acquire, where t_1 and t_2 are inter-pulse delay times. When the first 180° pulse is applied after time t_1, a spin echo forms at time $2 \times t_1$. When a second 180° pulse is applied after time t_2, the spin echo formed at $2 \times t_1$ is refocused into a second spin echo at time $2 \times t_1 + 2 \times t_2$, producing the signal that corresponds to the volume of interest. As in STEAM, crusher gradients are used in PRESS to remove the unwanted coherences.

Although STEAM can be used with shorter echo times for the observation of short T_2 metabolites, PRESS offers a factor of two times greater signal-to-noise, is less sensitive to motion and diffusion, and is not susceptible to the effects of multiple quantum coherence [36]. The use of longer echo times with PRESS also improves water and lipid suppression, but with improved gradient technology, echo times of the PRESS sequence can be reduced to that of STEAM to exploit the increased chemical information that can be obtained at shorter echo times. Recently, modified PRESS sequences for single voxel MRS and MRSI with very short echo times have been described using asymmetric rf pulses as well as optimized design and timing of the PRESS sequence [37].

Improved Volume Selection and Outer Volume Suppression

Spectroscopy studies in the body are critically dependent on accurate volume selection, since the region of interest is often adjacent to regions of lipid or air-tissue interfaces, which can significantly impair spectral quality. A recent technical advance for ^{1}H MRS has been the substitution of optimally shaped rf pulses, e.g. Shinnar-Le Roux pulses [38], in place of conventional sinc-shaped pulses for improved volume selection in PRESS acquisitions. Although low tip angle pulses can produce reasonably good slice profiles, optimized pulses are essential for 90° and especially 180° excitations [38]. Water saturation performance can also be improved using shaped pulses; however, due to the imperfect excitation profiles of the PRESS spin-echo pulses, even with Shinnar-Le Roux pulses, significant contamination from lipids outside the PRESS selected region can still occur. Several groups have used outer volume suppression (OVS) sequences to better conform the volume of interest [39–43]. These sequences utilized optimized pulses or special excitation schemes to shape the excitation volume to the region of interest. However, due to the non-rectangular suppression profiles of these pulses residual unsuppressed water and lipid signals at the band edges often rendered large portions of the spectral array unusable.

Quadratic phase pulse designs, e.g. very selective suppression (VSS) pulses [44], can provide excellent spatial selectivity, high effective bandwidths, and improved B_1 and T_1 insensitivity compared to conventional OVS pulses. VSS pulses can be inserted just before the PRESS excitation pulses and are used to better define the edges of the PRESS box. Additional VSS pulses can also be graphically prescribed in order to shape the selected volume to the region of interest to exclude regions of lipid or air tissue interfaces. Because of the imperfect PRESS excitation profile, the effects of chemical shift misregistration and the rounded edges of the PRESS selected volume can be dramatically reduced by overprescribing the PRESS selection by $\sim$20–30% and applying the VSS pulses to define the desired dimensions of the box as shown in Figure 1. The use of graphical VSS pulses to exclude periprostatic lipids in the prostate is illustrated in Figure 2A and B.

Water and Lipid Suppression

In order to detect the resonances of biological interest, the 110 molar water resonance must be suppressed by approximately 1000–10,000 fold and spectral contamination from lipids outside the volume of interest must be minimized as much as possible. Good shimming is absolutely essential for water and lipid suppression. Although automated shimming routines are often adequate and should be used as a starting point, it is well worth the extra time to manually shim and visually assess the shape of the water resonance and the FID. The ability to obtain a narrow water line width ($<$10 Hz) is also dependent upon the proper placement of the PRESS or STEAM box. When there are large differences in magnetic susceptibility, which can be caused by air-tissue or bone-tissue interfaces or the presence of radioactive seeds, it may be impossible to obtain adequate shim. If an adequate shim cannot be obtained in less than 5 min, the volume of interest should be re-prescribed and shimmed again, or the spectroscopy exam should be aborted. Prior to starting the MRS sequence, the water and lipid suppression pulses should be turned on in the pre-scan window to ensure that adequate suppression is being achieved.

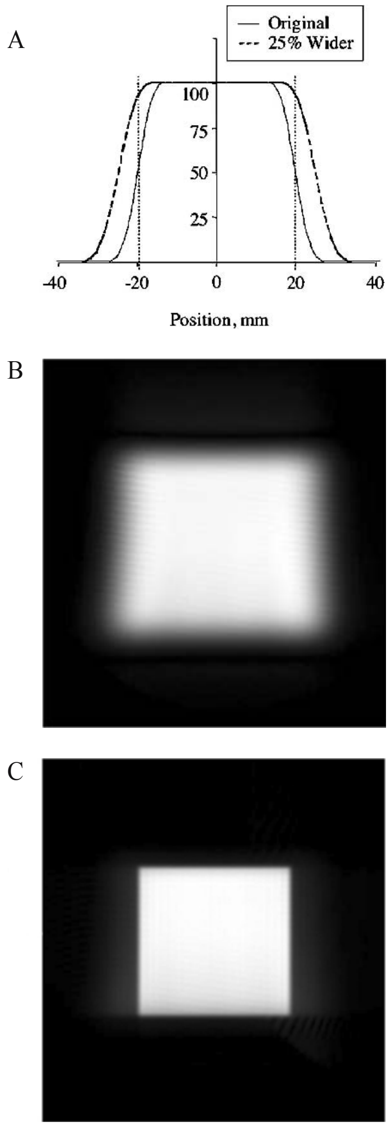

Fig. 1. Imperfect excitation profiles and compensation strategies. (A) Modeled excitation profile based upon the General Electric 90-PRESS excitation pulse, designed for a 40 mm width (solid line) and an identical pulse profile overprescribed by 25% (dashed line) at 1.5 T. An ideal pulse would be perfectly rectangular with 100% excitation at the edges (dotted lines at ±20 mm); however as prescribed the edges are only 50% excited at ±20 mm. For the overprescribed pulse, the edges are 93% excited at ±20 mm. (B) Image of a 40 × 40 × 40 mm^3 PRESS selected volume, overprescribed 20%. (C) Image of the PRESS selected volume shown in (B) with six VSS pulses added, yielding a very uniform excitation profile.

Techniques for water suppression have usually involved frequency selective saturation pulses (e.g. CHESS) [45]. Lipid suppression can be achieved by the selective excitation of a region of interest or by a combination of frequency and/or spatially selective pulses and selective inversion (STIR) [46]. These approaches require optimization for each individual study and often demonstrate inadequate water and lipid suppression, resulting in baseline artifacts and difficulty in quantifying metabolites. Recently, band selective inversion with gradient dephasing (BASING) pulses have been developed for combined water and lipid suppression, and have demonstrated suppression factors over 100 times greater than CHESS and STIR [47].

Spectral-Spatial Pulses

Spectral-spatial echo-planar spin-echo (EPSE) pulses simultaneously excite a selected frequency range and a selected volume, with the added advantage of reducing the chemical shift dependence of the PRESS volume [48]. Water and lipid suppression are not needed since their frequency ranges are simply not excited. Schricker *et al.* recently developed dual band spectral-spatial pulses which completely exclude lipid but allow for a partially excited water resonance for phase and frequency referencing [48]. This partial water signal can also be used to distinguish the absence of detectable metabolites due to therapy or atrophy from a technically failed study.

Chemical Shift Imaging

Single voxel MR studies are limited in the information they can provide and often suffer from improper or imprecise localization because their location is determined from MR images that cannot differentiate between tissue types. Furthermore, it is very difficult to attain perfect placement of the localized volume without spectral contamination from adjacent tissues, even when the region of interest is the same size or even slightly larger than the selected voxel size. Another limitation of single voxel studies is the inability to assess the spatial distribution of the metabolic changes. For heterogeneous or multi-focal lesions, particularly in prostate cancer, the exact choice of voxel size and position has a critical impact on the spectra acquired and their interpretation. To overcome the limitations of single voxel techniques, 3D phase encoding techniques have been added to PRESS or STEAM localization schemes [49,50] to provide localized spectra from arrays of multiple contiguous voxels with improved signal-to-noise. These techniques are referred to interchangeably as chemical shift imaging (CSI) or MRSI.

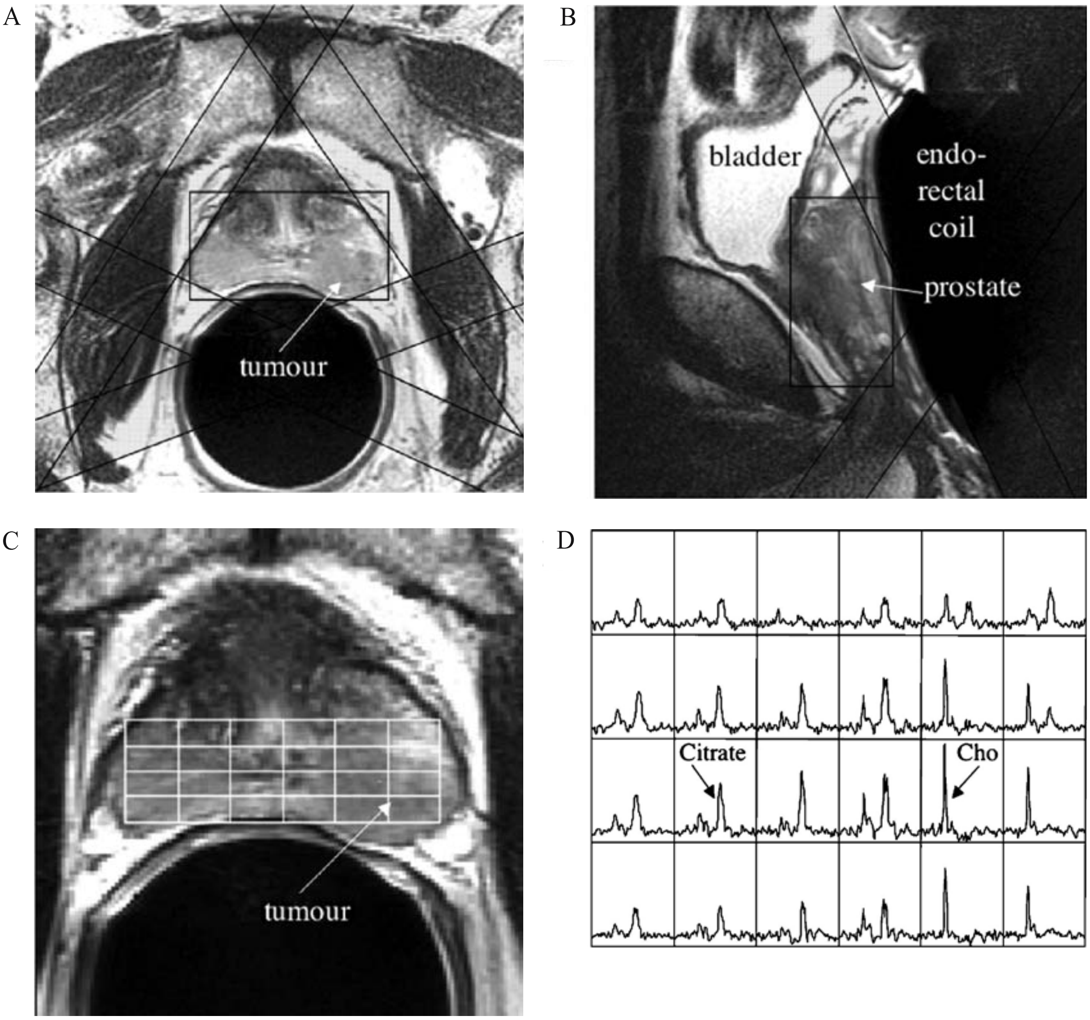

Fig. 2. Combined MRI/3D-MRSI of the prostate at 1.5 T. (A) Axial and (B) sagittal T_2-weighted images of the prostate showing the locations of the PRESS box and graphically prescribed VSS bands. (C) Axial T_2-weighted image and 3D-MRSI spectral grid which has been zero-filled in the anterior–posterior dimension. (D) Corresponding 3D-MRSI spectral array showing the presence of an aggressive appearing tumor (very elevated Cho and reduced citrate) on the left side of the gland (right side of the image). *Note:* Spectral array is one out of typically seven or eight acquired throughout the prostate.

Surface Coils

The ability to achieve high sensitivity, specifically high signal-to-noise, in the body is often impeded by the deep location of the organs within the body. While in principal body coils provide uniform excitation, they are not sensitive enough to be used for signal reception. Consequently, surface coils have been developed for signal reception, and for ^{31}P MRS applications, both transmission and reception. For prostate spectroscopy, a rigid or inflatable endorectal probe is essential to achieve the necessary sensitivity and to reduce peristaltic motion. For other organs, larger arrays of coils are typically placed over the torso or abdomen. These arrays include rigid frames of coils that are placed anteriorly and posteriorly, flexible coils which can be molded to the body allowing closer placement to regions of interest, and specialized breast coil arrays which circle the breasts and extend into the axilla for the supine patient. Many surface coils are now commercially available from a number of vendors (e.g. USA Instruments Inc., MRI Devices Corporation, and Medrad Inc.).

While surface coils and phased arrays of surface coils can provide much better sensitivity than the body coil, their sensitivity varies with position and decreases with increasing distance from the coil. If interpretation of spectra is to be based on ratios of resonance intensities or areas then the inhomogeneous reception profile of the surface coil can generally be neglected. However, the absolute amplitudes of individual metabolite peaks cannot be directly compared without taking into account the surface coil reception profiles. Like MR images, spectra can be at least partially corrected for inhomogeneous reception profiles by numerical evaluation of the Biot–Savart law [51]. Simplistically, the coil is modeled as a series of finite elements of various lengths from which a theoretical reception profile is calculated and the spectra are then divided by the theoretical profile. In practice, such correction algorithms need to take into account the anatomical location of the coil with respect to the location of the voxels to be corrected. The quality of the coil correction can then be evaluated by applying the same algorithm to the corresponding MR images, and by comparing the corrected images to the coil map. If the location of the coil map is incorrect, the images will contain very distinct hypointense (dark) or hyperintense (bright) spots, and the position of the coil should be re-determined and the algorithm reapplied. An alternative approach is to acquire proton density weighted images, which demonstrate the sensitivity profile of the coil, and use these to correct the data [52].

In heteronuclear and high field (e.g. 4 and 7 T) MRS, combined transmit/receive surface coils are required and inhomogeneous excitation profiles become a major issue. Specifically, an inhomogeneous excitation profile results in different locations experiencing different nutation (flip) angles, which causes poor or inadequate spatial selection and chemical shift misregistration. One way of overcoming problems associated with inhomogeneous excitation profiles is to excite with a much larger surface coil than that used for signal reception. Another way to overcome the problems with inhomogeneous excitation profiles of surface coils is to use adiabatic rf pulses, such as B_1 insensitive rotation (e.g. BIR-4) pulses [53]. Adiabatic pulses produce a uniform flip angle, typically 90° or 180°, across a region of interest despite variations in B_1, provided that the rf power is above a minimum threshold value. Adiabatic pulses are highly versatile and can be exploited for spatial localization [e.g. localization by adiabatic selective refocusing (LASER) [54]], as well as water suppression and OVS [e.g. B_1-insensitive train to obliterate signal (BISTRO) [43,55]].

Motion

Respiratory and peristaltic motion can also be major problems in body spectroscopy. In the prostate, peristaltic motion is reduced by the use of an inflatable endorectal coil. Because the prostate is directly beneath the bladder, as shown in Figure 2B, additional motion may be caused by the bladder filling up during the course of the examination. To minimize this, patients are asked to refrain from drinking (especially caffeinated beverages) for 2–3 h prior to the exam. In the breast, motion is reduced by having the patient lay supine on a breast coil, supported by the chest, resulting in the breasts remaining relatively free of respiratory motion. Nonetheless, one study showed that in 20 breast and abdominal tumors, 30% moved 6–23 mm, while the diaphragm and fatty tissues of the gut typically moved $\sim$15–20 mm [56]. Recently, it has been reported that breathheld MRS can significantly reduce phase and frequency shifts and outer voxel contamination due to respiratory motion [57], while the use of navigator echoes can aid with retrospective motion correction [58].

Data Processing and Display

Single voxel MRS data can often be processed and displayed using commercial software packages designed for conventional NMR spectroscopy, provided that the header can be interpreted or removed. Basic data processing involves Lorentzian and/or Gaussian apodization of the FID to enhance resolution and/or signal-to-noise, baseline correction, zero-filling, and Fourier transformation of the data. Phasing and frequency referencing are then performed manually on the resulting spectra. Because MRSI data may contain hundreds of useable spectra, completely automated and robust data processing algorithms are essential. In addition to the basic data processing steps just described, the data must be reconstructed to correctly reproduce the spatial dependence of the data [59] and can also be spatially zero filled as shown in Figure 2C and D. After the spectra have been Fourier transformed, automated baseline, phase, and frequency corrections can then be applied using water as a reference or by using prior knowledge of the approximate relative positions of the major peaks in the spectrum. Peak areas may be estimated by integration across fixed frequency ranges, by fitting baseline subtracted data as a sum of components with particular lineshapes [60–63], or using linear combinations of model *in vitro* spectra [64].

Several different approaches have been used to display the information from multi-dimensional localized spectra and to correlate spatial variations in metabolites with the anatomy [50,65–68]. These include superimposing a grid on the MR image and plotting the corresponding arrays of spectra, and calculating images of the spatial distribution of metabolites to overlay on the corresponding MR images. These formats provide an excellent summary of the spatial distribution of different metabolites enabling rapid identification of regions of suspected abnormal signal and facilitating correlation with the anatomy. Additionally, since 3D volume MRI and MRSI data are collected, the data can be viewed in any plane (axial, coronal, or sagittal), and the spatial position of spectroscopic voxels can be selected retrospectively via "voxel-shifting," using the appropriate mathematical weighting of the raw data based upon the translation property of the Fourier transform [69,70]. This method of interactive analysis will be the way that MRI/MRSI data is used in the future and should reduce interpretative errors associated with the overlap of normal and abnormal tissues.

Data Interpretation

Interpretation of spectroscopy and spectroscopic imaging data requires both knowledge of what constitutes a clinically interpretable spectrum and an understanding of the underlying biochemistry and morphology that result in the observed changes. ^{1}H spectra are considered clinically interpretable if they are not contaminated by insufficiently suppressed water or lipid and have resolvable metabolite peaks with peak area to noise ratios of greater than 5 to 1. Metabolic criteria must then be established to distinguish abnormal from normal metabolism and then validated using a pathologic "gold standard." In the prostate, the (Cho + Cr)/Cit ratio discriminates prostate cancer from benign glandular tissues with high specificity [12]. In the other organs of the body, similar metabolic criteria must still be established. *Ex vivo* high-resolution magic angle spinning (HR-MAS) spectroscopy and quantitative pathologic analysis of intact surgical or biopsy tissues can aid in understanding the relationship between metabolism and tissue composition [71] and thereby help with the identification of the appropriate metabolic criteria. Finally, the metabolic criteria used to identify residual or recurrent disease often change following therapy [8]. Treatment effects typically result in an overall reduction in the signal-to-noise of all metabolites, which underscores the need to be able to distinguish an absence of metabolites (termed "metabolic atrophy") from a technically failed study.

Applications in the Prostate, Breast, and Liver

To date, *in vivo* MRS has been applied to the prostate [12,22], breast [4,25,72,73], liver [74,75], kidney [76,77], colon [78], heart [79–81], skeletal muscle [82–84], sarcomas [85,86], and non-Hodgkin's lymphomas [10,87,88]. In the following sections, specific applications in the prostate, breast, and liver are described and ^{1}H MRS examples are shown.

Prostate Cancer

The earliest MRS studies of the human prostate involved ^{31}P spectroscopy using a dual tuned (^{31}P/^{1}H) transmit/receive endorectal probe [22,89,90]. The proton frequency was used to image the location of the coil and obtain a homogeneous field of view, prior to performing phosphorus spectroscopy. These studies demonstrated the ability of ^{31}P MRS to detect metabolic differences between normal, hyperplastic, and malignant prostate tissues. Specifically, the ^{31}P MR spectra taken from regions of prostate cancer were characterized by increases in the phosphomonoester to β-NTP ratio and decreases in the PCr to β-NTP ratio relative to healthy prostate tissues [22,89,90]. Additional studies using murine models of prostate cancer also identified ^{31}P spectral characteristics that may be related to the hormone sensitivity, radiation sensitivity, and metastatic potential of the cancer [16]. However, these early ^{31}P MRS studies of the prostate were limited by coarse spectral localization and spatial resolution due to the inherent insensitivity of ^{31}P MRS. Therefore, most of the clinical prostate studies performed to date have utilized a combination of high spatial resolution MRI and ^{1}H MRSI.

High-resolution T_2-weighted imaging, using combined endorectal and pelvic phased array coils, has demonstrated good sensitivity but relatively poor specificity for identifying prostate cancer, because numerous other conditions, including prostatitis, benign prostatic hyperplasia, and treatment effects can all mimic cancer. Prior to therapy, the addition of 3D-MRSI to anatomical MRI has been shown to improve the localization [2] and staging [3] of prostate cancer, provide a measure of prostate tumor volume [91], and provide an assessment of prostate cancer aggressiveness [92]. The ability of combined MRI/MRSI to identify residual or recurrent prostate cancer after hormone deprivation [8,9] and radiation therapy [93,94] has also been described.

Healthy glandular prostate tissue demonstrates two unique metabolic markers, citrate and spermine, that are produced by highly specialized epithelial cells and secreted into the prostatic ducts that empty into the ejaculate. Both citrate and spermine are reduced or absent in regions of prostate cancer, due to both biochemical changes and a loss of the prostate's normal ductal morphology [95–98]. Although the citrate resonance is completely resolved, its detection is complicated due to strong coupling. At 1.5 T, under good shimming conditions, polyamines are seen as a hump resonating between Cho and creatine, while in regions of cancer, the reduction or loss of polyamines is observed as an increase in the discrimination between Cho and creatine.

At our institution, axial high-resolution T_2-weighted images (3 mm slice thickness, no intersection gap) are used to select a PRESS volume (typically 50–100 cm^3) that encompasses the entire prostate, but excludes periprostatic lipids, the seminal vesicles which contain very high levels of GPC, and the air tissue interface of the rectum. The PRESS box is overprescribed by 20–30% in all three dimensions and then six VSS pulses are used to define the desired edges of the PRESS box. Six additional VSS pulses are graphically prescribed to eliminate contamination from surrounding lipids (Figure 2A and B). With a typical voxel size of ∼7 mm on a side (0.34 cm^3), $16 \times 8 \times 8$ step phase encoding ($112 \times 56 \times 56\ \text{mm}^3$ field of view) is performed with a 1 s repetition time for a total acquisition time of ∼17 min.

Spectral data from a MRI/MRSI staging exam acquired under these conditions are shown in Figure 2. Figures 2A and B show the location of the PRESS box and the locations of the graphical VSS bands. Figure 2C shows a portion of the 3D spectral grid, which has been zero filled in the anterior/posterior direction, and Figure 2D shows the corresponding MRSI spectral data. As can be seen, the right side of the gland (left side of the image/array) demonstrates fairly normal metabolism with high levels of citrate and low levels of Cho. However, the left side of the gland (right side of the image/array) demonstrates very elevated levels of Cho and in some areas a complete absence of citrate, consistent with the presence of an aggressive prostate tumor. The patient subsequently went on for a transrectal ultrasound (TRUS) guided biopsy and was diagnosed with Gleason 4 + 3 prostate cancer.

The interpretation and utility of prostate MRSI can be complicated by the presence of chronic inflammation (prostatitis) [99], which appears metabolically similar to prostate cancer. Additionally, post-biopsy hemorrhage can persist for 6–8 weeks or more after biopsy and demonstrates a reduction or absence of citrate and polyamines due to the disruption of prostatic ducts, and in worse cases results in a complete absence of all prostatic metabolites [100]. Regions of hemorrhage are usually identified as bright areas, and less frequently dark areas, on axial T_1-weighted images and these can be used to exclude suspected regions from the MRSI data analysis. Following therapy, the time course of treatment-induced metabolic changes must be taken into account when interpreting the data. For example, hormone deprivation has a very fast impact on prostate metabolism and often results in a total loss of citrate and polyamines within 16 weeks [8]. Conversely, radiation therapy has a much slower impact on prostate metabolism and may take 1–3 years to achieve metabolic atrophy. In either case, the presence of elevated Cho relative to creatine appears to be the best current indicator of recurrent prostate cancer.

Breast Cancer

For breast cancer, one of the critical clinical questions is whether the lesion detected on screening is benign or malignant. About 75% of the breast lesions detected by mammography and about 50% of the enhancing lesions detected by contrast-enhanced MRI are pathologically benign [101]. Sonographic classification of benign and malignant tumors has low specificity (about 30%) as well [102]. Recent advances in contrast-enhanced MRI methodology and interpretation have greatly improved the ability to differentiate malignant from benign breast tumors. However, there still remains a clinical need for improved specificity [103,104], which spectroscopy may be able to provide [4].

Breast spectroscopy has lagged behind prostate and brain spectroscopy because of the presence of mobile lipids and a lack of multiple metabolic markers. Early ^{31}P MRS studies typically observed increased phosphomonoester, phosphodiester, and sometimes PCr levels in breast cancer vs. normal tissues [105]. However, because of the poor sensitivity of ^{31}P MRS combined with the decreasing size of breast tumors due to early detection, ^{1}H MRS is now being primarily used. Typical breast MRS studies use a single voxel ($\sim 1 - 27\ \text{cm}^3$) [4] localization technique such as STEAM or PRESS with the intent of selecting signals from the lesion of interest and excluding signals from the surrounding adipose tissue and normal parenchyma [4]. However, due to the magnitude of lipid resonance in the breast, gradient induced sidebands of the lipid resonance can cause both positive and negative artifacts in the Cho region of the spectrum. Recently, a technique called "T_E-averaging," based upon oversampled 2D J-resolved spectroscopy [106], has demonstrated the ability to separate lipid induced sidebands and provide increased sensitivity for the study of small or irregularly shaped lesions [72]. An example of the spectral improvement provided by T_E-averaging is shown in Figure 3.

Currently, the interpretation of breast ^{1}H MRS data is relatively simple and mainly involves determining whether Cho is present (malignant) or absent (benign) [4]. This observation is consistent with the high PC content of human breast cancer cells, which is 10-fold higher than that of normal human mammary epithelial cells [107]. However, Stanwell *et al.* found that 20% of normal volunteers also demonstrated detectable Cho, leading to an overall sensitivity and specificity of 80 and 86%, respectively, when Cho presence alone is used to define cancer [108]. Additionally, smaller tumors tend to be diagnosed as benign (false–negative) because of the lack of a detectable composite Cho signal [4]. Other complications in the interpretation of breast spectra have primarily been technical and associated with poor spectral quality [4,109]. The utility and robustness of breast spectroscopy can be improved by increasing the Cho signal-to-noise

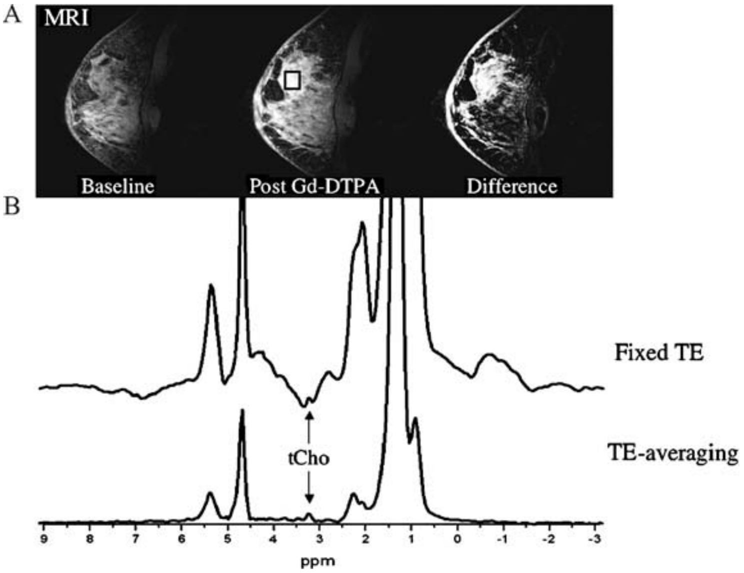

Fig. 3. (A) T_1-weighted image, dynamic contrast-enhanced image, and difference image of a poorly differentiated adenocarcinoma of the breast acquired at 4.0 T. through the use of higher sensitivity coils, the addition of new metabolic markers, and the use of improved pulse sequences and higher field human scanners.

MRS of the Liver

The liver is the most biochemically complex organ in the human body, and in addition to being the second most common site of cancer metastasis (after lymph nodes) [110], the liver is subject to a variety of non-malignant diseases including inflammation, hepatitis, cirrhosis, and fatty liver disease. The majority of liver MRS studies have looked at fat content and have shown that proton MRS of liver fat correlates well with *ex vivo* liver fat measurements [111]. Lipid levels have been shown to change with cancer [28,29], metabolism [112,113], and non-alcoholic fatty liver disease (NAFLD) and non-alcoholic steatohepatitis (NASH) [7,114,115]. Example single voxel ^{1}H MR spectra from a healthy individual and from a patient with fatty liver disease are shown in Figure 4. While the body mass index of these two individuals were similar (26 vs. 27, respectively), the lipid to water ratio is much greater in the subject with fatty liver disease.

Because of the problem of motion in the abdomen, liver MRS is typically performed as a single voxel technique, with a surface coil phased array used for reception. In the case of diffuse disease (e.g. fatty liver disease), where the location within the organ is not critical, the voxel should be placed at least 1 cm from all edges of the liver to reduce the chance of contamination from signals outside the liver. In the superior/inferior direction, the voxel should be placed such that it will remain in the liver throughout respiration. This can be ascertained by comparing breathheld images acquired at end-expiration to those at end-inspiration. During pre-scanning, the signal amplitude should also remain relatively constant from pulse to pulse. To account for small shifts in position over time, MR spectra can be saved individually before averaging. These individual MR spectra can then be phase and frequency aligned before summation to account for some respiratory motion.

Summary

MR spectroscopy and spectroscopic imaging are promising techniques for the metabolic assessment of cancer and other diseases in the body. However, spectroscopy in the body is challenging due to motion and the deep location of many organs. The critical considerations when performing spectroscopy in the body include the choice of: nucleus (^{1}H is preferred at 1.5 T due to high sensitivity, but ^{31}P and ^{13}C may be valuable at higher field); single voxel vs. multi-voxel (CSI or MRSI) approach; localization scheme (e.g. PRESS, STEAM, LASER); water and lipid suppression (e.g. BASING, CHESS, STIR) and OVS techniques (e.g. VSS pulses); surface coils; and data display and analysis tools. Proper spectral interpretation based upon a pathologic “gold standard” and knowledge of the impact of therapy on metabolism are both critical for evaluating the clinical utility of new MRS applications in the

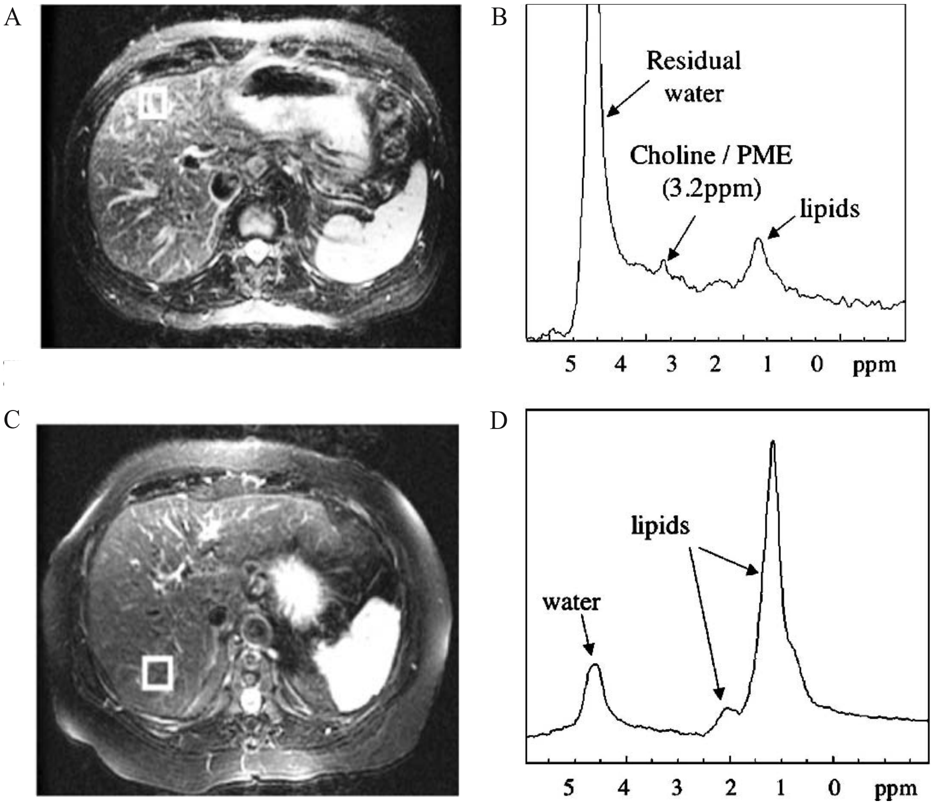

Fig. 4. Axial T_2-weighted image and $2 \times 2 \times 2$ (8 cm^3) single voxel ^1H spectra acquired from the liver of a normal volunteer (A and B) and a patient with NAFLD (C and D). Data were acquired at 1.5 T using PRESS with VSS pulses and CHESS water suppression (no lipid suppression), with 128 transients, $T_R = 2500$ ms, and $T_E = 35$ ms. Voxels were prescribed >1 cm from the edges of the liver, avoiding vessels, and spectra were individually phased and frequency shifted before averaging.

body. The increased sensitivity provided by higher field MR scanners, improved pulse sequences and technology, and the ability to include additional metabolic markers will also have a major impact on the clinical potential of body spectroscopy in the future.

Acknowledgments

The authors wish to acknowledge and thank Drs. Michael Garwood and Patrick J. Bolan, Center for Magnetic Resonance Research, University of Minnesota School of Medicine, Minneapolis, for providing the breast figure presented in this chapter, and Dr. Aliya Qayyum, Department of Radiology, University of California, San Francisco, for providing the liver figures presented in this chapter.

Glossary of Terms

BASING	Band selective inversion with gradient dephasing
BIR	B_1-insensitive rotation
BISTRO	B_1-insensitive train to obliterate signal
CHESS	Chemical shift selective saturation
CSI	Chemical shift imaging
EPSE	Echo-planar spin-echo
FID	Free induction decay
HR-MAS	High-resolution magic angle spinning
ISIS	Image selected *in vivo* spectroscopy
LASER	Localization by adiabatic selective refocusing
MRI	Magnetic resonance imaging
MRS	Magnetic resonance spectroscopy

MRSI	Magnetic resonance spectroscopic imaging
NAFLD	Non-alcoholic fatty liver disease
NASH	Non-alcoholic steatohepatitis
NOE	Nuclear overhauser enhancement
OVS	Outer volume suppression
PPM	Parts-per-million
PRESS	Point resolved spectroscopy
STEAM	Stimulated echo acquisition mode
STIR	Short time inversion recovery
T_1	Longitudinal (spin–lattice) relaxation time
T_2	Transverse (spin–spin) relaxation time
TRUS	Transrectal ultrasound
VSS	Very selective suppression
WALTZ	Broadband decoupling scheme

MR-Mammography

W. A. Kaiser

Institute for Diagnostic and Interventional Radiology, Friedrich Schiller University, Jena, Germany

Introduction

MR-Imaging (MRI) of the breast, or MR-Mammography (MRM), has probably been one of the most controversially discussed indications for MRI in the last 20 years. Whereas MRI of the brain and spine or of the musculoskeletal system was rather quickly accepted as a valuable and helpful tool to detect diseases, descriptions of MRM initially ranged from "probably not useful" to "unclear" to "wait and see". However, in the last 5 years or so a striking wave of publications has underlined the significant additional information provided by MRM.

In this chapter a brief overview about the history of MRM is followed by a description of the pathophysiological basics and the present status and indication. An overview of the different techniques follows and the description of future challenges will finalize this report.

History of MRM

The development of MRM included several phases:

MR-Tomography in general had first to be developed, then special *breast coils* (single breast coils, followed by double breast coils later combined imaging/interventional coils) built and optimized. *Contrast media* were used at first in spin–echo sequences, later in sophisticated the so-called "*dynamic*" *techniques* using gradient echo sequences for a better differential diagnosis.

1. By 1971 different relaxation times in tumor tissue in comparison to normal tissue were measured using *in vitro* experiments [1]. However, MRI of the human body was possible only after the application of local gradient fields [2]. First, tissue samples of the breast were published by Mansfield *et al*. [3]. These tissue samples were taken about 90 min after operation. First, *in vivo* images of the breasts from 65 patients (128 breasts) including seven cancers was undertaken using whole-body MR-machines in 1982 [4]. In these reports a whole-body scanner with a field strength of 0.045 T was used and patients imaged in a supine position providing two proton-density-weighted images and six T_1-relaxation-time measurements per patient. In 1983, El Yousef *et al*. [5] published results from 2 patients using an experimental surface coil in a field strength of 0.03 T and reported a reduced signal intensity of both cancers. In a following publication of the same group [6] in 1984, images of 10 volunteers and 45 patients were reported describing a reduced signal intensity of breast lesions in spin echo and inversion-recovery sequences.
2. From 1983, onwards special breast coils were developed which were used only for breast imaging and later sold commercially. Until 1986 only single breast coils were available [7,8]. After first-disappointing trials in a supine position the examinations were performed in a prone position to minimize movement and artefacts caused by breathing. However, at that time the available spin-echo- and inversion-recovery sequences did not allow a definite detection and differentiation of small lesions in all cases, yet the advantage of imaging in thin slices in any orientation in a variable soft tissue contrast without X-rays was already clear [9–12]. Further progress was made with the development and introduction of the MR-contrast-medium Gadolinium-DTPA [13]. Experiments were possible in analogy to computer tomographic results using ionized X-ray contrast medium and radioactive iodine uptake from the mid seventies [14,15]. The first group to acquire and use contrast medium was Heywang *et al*. [16]. Initially spin-echo sequences in relatively long examination times and high contrast dosages were applied and reported; however, the uptake of contrast medium of cancers, normal tissue, and proliferative changes could not be differentiated sufficiently. After the introduction of fast echo gradient sequences [17] the first dynamic examinations using repetitive measurements of the same slices before and, in short time intervals, after contrast injection were established [18,19]. However, how to achieve better differentiation between benign and malignant lesions was a major issue amongst scientists [20]. The following development of a double breast coil [21] allowed routine measurements of both breasts of a patient in a single examination in a good signal-to-noise (SNR) ratio. These initial steps were followed by a phase of evaluation of dynamic techniques using different measurement sequences and dosages, which was mainly performed in Europe. The result of the enormous variety of measurement techniques was, at

© 2008 *Springer.*

first, Babylonian confusion and a broad range of opinions about the usefulness of MRM [22–72], especially before 1995.

3. Using MRM small lesions of a few millimeters could be detected, which were often not seen by X-ray or ultrasound. Therefore, a need for the development of interventional MR procedures was rising, at first for positioning of markers, later for biopsy and therapeutic removal [73–80]. These techniques currently require an additional MR image to be taken later, i.e. a second measurement and a repeated use of the MR-device and contrast injection. At present single breast biopsy coils in the so-called "closed" as well as in "open" MR-devices are tested. A bilateral coil for combined imaging and simultaneous intervention has been used in clinical tests since 1997 [81].

Pathophysiological Background of MRM

The secret of the very high sensitivity of MRM for the detection of breast lesions is the detection of tumor-based angiogenesis [82–84]. It is well-established that any tumor of more than 2 mm needs an increased perfusion to selectively direct nutrients towards the malignant tumor. Fifty years ago it was found that the implantation of breast cancer cells induces new micro-vessels after 3 days post implantation. Meanwhile numerous publications especially from Judah Folkman, have clarified that human breast cancers, like other malignant tumors, possess the angiogenentic power as well [85–91]. Over 20 years ago [92] it was established that, in a "far" distance of 3 cm from the cancer, an increased concentration of tumor angiogenetic factors can be measured. Probably induced by

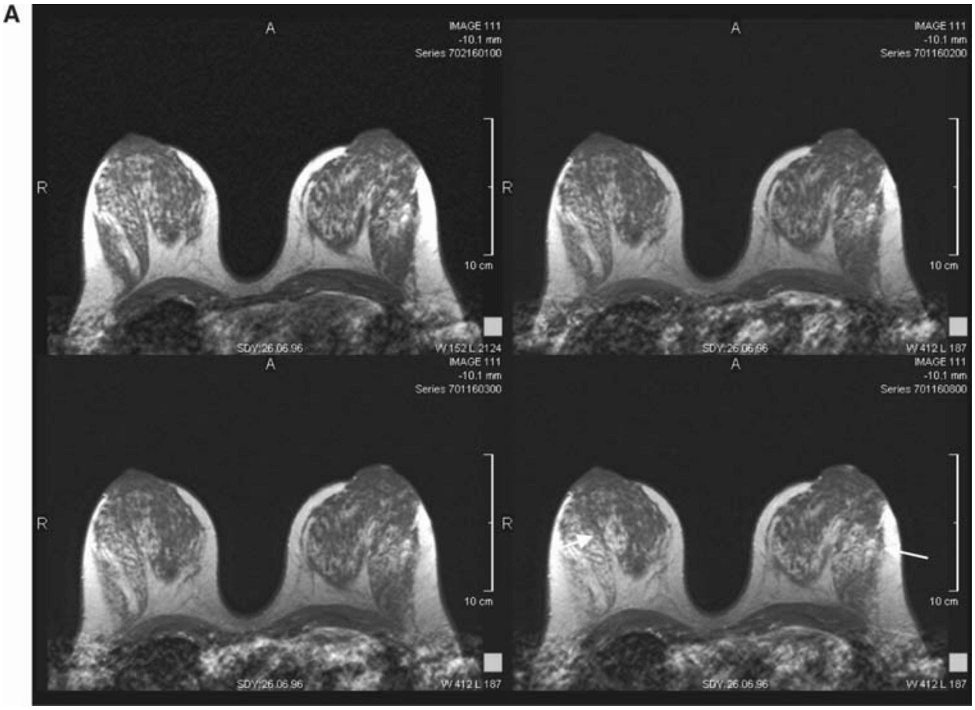

Fig. 1. Normal enhancement, Inflow-phenomenon (40-year-old patient, dense breast) (A) Original dynamic scans showing the uptake of contrast over 7 min (upper left = precontrast, upper right = 1-min-postcontrast, lower left = 2-min-postcontrast, lower right = 7 min postcontrast), slow progressive enhancement especially in the outer portions of the parenchyma, bilateral, symmetric enhancement. The contrast usually arrives via lateral thoracic artery in the outer upper quadrant at first (inflow phenomenon) (arrows). (The left breast is displayed on the right side of the image, the right breast is displayed on the left side of the images.) (B) The inflow phenomenon is best delineated in the corresponding subtraction images (arrows) (upper left = subtraction 1-min-postcontrast minus precontrast, upper right = subtraction 2-min-postcontrast minus precontrast, lower left = subtraction 3-min-postcontrast minus precontrast, lower left = subtraction 7-min-postcontrast minus precontrast). (C) So-called "mosaic-image" (upper left = precontrast, upper right = 1-min-postcontrast, lower left = subtraction 1-min-postcontrast minus precontrast, lower left = T_2w-TSE image; all images in identical sclice positions).

Fig. 1. (*Continued*)

hypoxia, acidosis, and many tumor angiogenetic factors, and eventually combined by an inactivation of the p53 suppressor gene, the so-called "tumor angiogenetic switch" is induced and new vessels arise through the sprouting of capillaries from pre-existing micro-vessels. Host capillaries dilate and become hyperpermeable, fibrin exudes through the leaky capillaries, proteinases, and collagenases break basal membranes, endothelial cells migrate across ruptures, form loops and canalize and finally a "functional neovasculature" called "tumor angiogenesis" is built.

Unique properties of tumor vessels are increased tumor blood volume, increased arterio-venous shunt formation, altered capillary bed transit time, increased interstitial pressure, and increased capillary permeability.

Among more than fifty so-called "tumor-angiogenetic factors" the vascular permeability factor (VPF), vascular endothelial growth factor (VEGF), and basic fibroblastic growth factor (bFGF) are most important.

Various pharmacokinetic models revealed that, in particular, differences in tumor vessel permeability are the

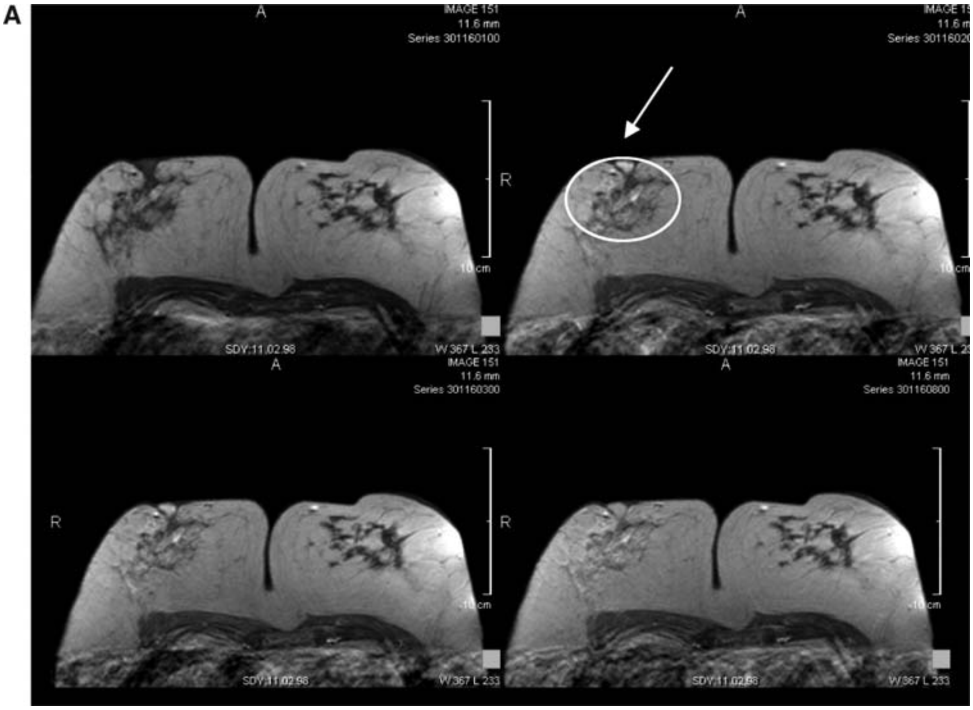

Fig. 2. Invasive lobular cancer and Lobular cancer in situ (LCIS, 78-year-old patient). (A) Original dynamic scans showing the uptake of contrast over 7 min (upper left = precontrast, upper right = 1-min-postcontrast, lower left = 2-min-postcontrast, lower right = 7 min postcontrast), strikingly enhancing area in a diameter of 1.3 cm behind the nipple in the right breast (arrow) with a maximum signal rise within the first minute after the injection of contrast followed by a decrease of signal intensity ("washout-phenomenon") which is very typical for a cancer. In addition to that, nearly the complete right parenchyma shows a reticular, network-like enhancement compared to the other non-affected left breast (ellipse). (B) This reticular enhancement (ellipse) can clearly be detected in the corresponding subtraction images besides the focal mass enhancement of the invasive cancer (arrow). Most of this network-loke enhancement representing LCIS is steadily continuously enhancing with confluent irregular lesions in late scans (upper left = subtraction 1-min-postcontrast minus precontrast, upper right = subtraction 2-min-postcontrast minus precontrast, lower left = subtraction 3-min-postcontrast minus precontrast, lower left = subtraction 7-min-postcontrast minus precontrast). (C) The "mosaic-image" (upper left = precontrast, upper right = 1-min-postcontrast, lower left = subtraction 1-min-postcontrast minus precontrast, lower left = T_2w-TSE image in identical sclice positions) shows the invasive cancer dark in T_2w-scans (arrow), whereas the LCIS is unspecific in T_2w-signal intensity (ellipse). The main hallmark for invasive cancer is a striking "washin" in a typical range for cancers followed by a "washout-phenomenon;" the main hallmark for non-invasive cancer is the asymmetric enhancement in relation to the opposite breast (both the invasive and the non-invasive cancer had not been described by X-ray mammography and ultrasound in this case).

Fig. 2. (*Continued*)

defining feature of tumor angiogenetically based uptake of contrast medium in breast cancer [93–96].

As a consequence of this pathophysiological basis MRM is looking for the type, the amount and the morphology of enhancement within the neighborhood of, and in, a lesion [97–102]. As mentioned above, malignant lesions are characterized by a tumor angiogenetic network of tumor-specific micro-vessels; thus, they show a rapid initial increase of signal intensity in T_1-weighted images (T_1w-images) after the injection of contrast medium within the first 1–2 min after injection, followed by a plateau, or the so-called "washout" effect, i.e. a decrease of signal intensity. This "washout" effect is probably caused by the arterio-venous-shunts within the angiogenetic network. Most benign tumors show a significantly different type of enhancement, either a slow progressive uptake or a very rapid increase with a further signal rise after the initial enhancement. However, about 20% of benign lesions (especially myxoid fibro-adenomas) might also show a strong initial enhancement followed by a plateau or a washout effect.

It is vital that the kinetic analysis is drawn only from the non-necrotic part of the tumor and that the maximum signal increase is used; a tumor contains all types of cells and compartments including haemorrhage, necrosis, and fibrosis besides vital malignant tumor cells. The so-called "wash-in"-phenomenon (i.e. the initial enhancement before the bending of the curve) is the most sensitive

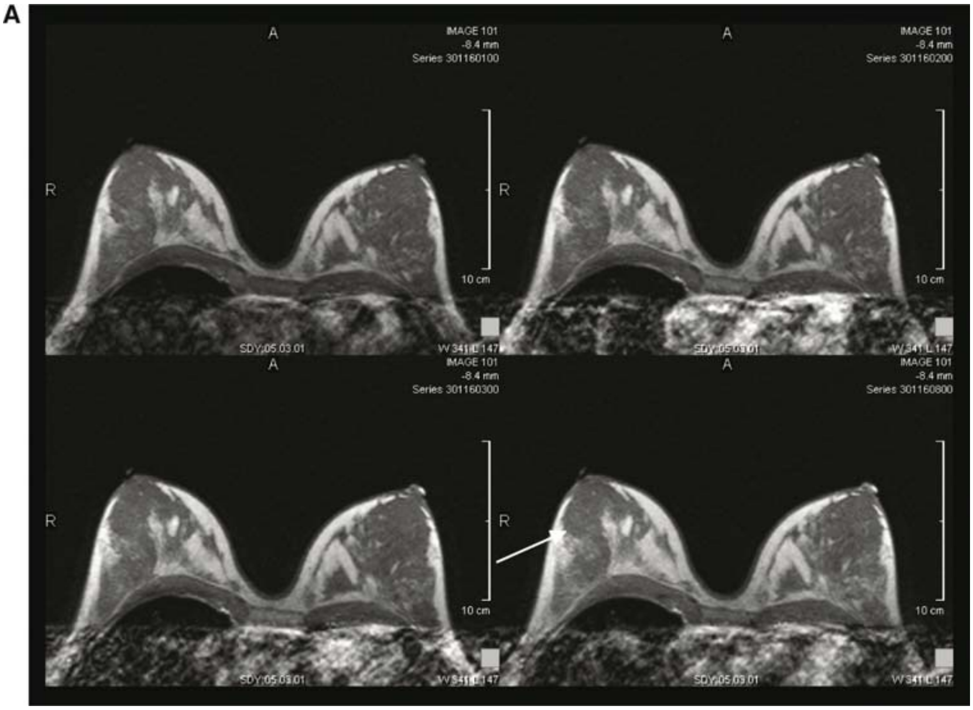

Fig. 3. Fibrous fibroadenoma (41-year-old patient with a lump in the lateral part of the right breast. The left breast is displayed on the right side of the image, the right breast is displayed on the left side of the image). (A) The original dynamic scans show a slow steady area of enhancement in the lateral portion of the right breast (arrow) without any cancer-like washin or washout-phenomenon. (upper left = precontrast, upper right = 1-min-postcontrast, lower left = 2-min-postcontrast, lower right = 7 min postcontrast). (B). The corresponding subtraction images (upper left = subtraction 1-min-postcontrast minus precontrast, upper right = subtraction 2-min-postcontrast minus precontrast, lower left = subtraction 3-min-postcontrast minus precontrast, lower left = subtraction 7-min-postcontrast minus precontrast) display this slow enhancement (arrow) better than the original images. In addition a slight motion artefact in the left breast. (C) The "mosaic-image" (upper left = precontrast, upper right = 1-min-postcontrast, lower left = subtraction 1-min-postcontrast minus precontrast, lower left = T_2w-TSE image in identical sclice positions). The T_2w-scan show the lesion in a dark signal intensity (arrow). Typical signal change of a fibrous fibroadenoma, i.e. a slow, steady enhancement without cancer signs, dark in precontrast and dark in T_2w-scans.

Fig. 3. (*Continued*)

parameter; the "washout" effect (i.e. the late signal decrease following the initial signal increase at the "cancer-corner") is the most specific parameter to diagnose a malignant tumor.

In addition to kinetic data, morphological signs have to be included for the distinction between benign and malignant lesions. As malignant tumors often show a "rim-enhancement" (i.e. the most enhancing vital tumor areas are in the outer rim of the lesions, because the centre consists mostly of necroses). In contrast to this, benign lesions usually enhance within the centre as well as, and as early as, in the border areas. Malignant tumors often show irregular borders and spiculation, whereas most benign lesions have sharply delineated, often polylobulated margins. Benign lesions might show clear, non-enhancing septations. The vast majority of cancers (98%) show low signal-intensities in the T_2-weighted-Turbo-Spin-Echo-images (T_2w-TSE-images), whereas the strongly enhancing myxoid fibroadenomas are more or less brighter than parenchyma in T_2w-TSE-images.

Malignant lesions often show the so-called "blooming-sign", i.e. an increasing enhancement in the neighborhood outside the lesion [100].

Meanwhile more than 20 different signs in the combined morphological and kinetic analysis enable a highly reliable discrimination between a benign and malignant

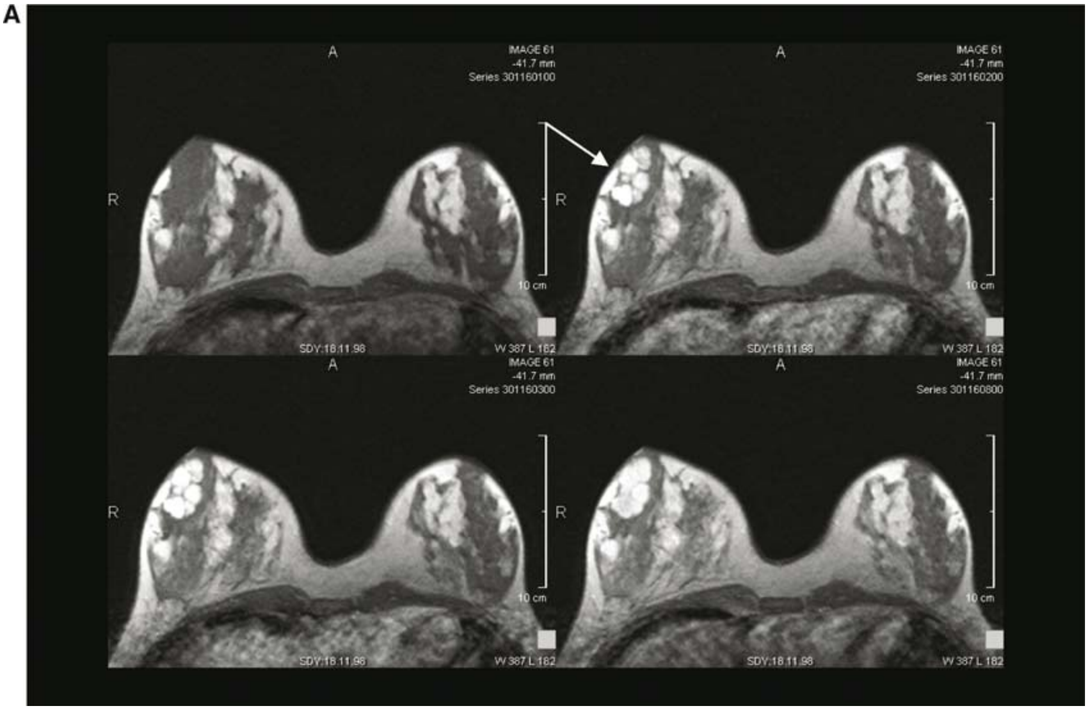

Fig. 4. Myxoid or "hyaline" fibroadenoma (22-year-old patient with a lump in the lateral part of the right breast. (The left breast is displayed on the right side of the image, the right breast is displayed on the left side of the images). (A) The original dynamic scans show a 3 × 4 cm multicompartmental area in the right breast; some compartments enhance suddenly and more intensively than cancers, some compartments enhance slower, some compartments show a plateau-phenomenon or even a washout-effect (upper left = precontrast, upper right = 1-min-postcontrast, lower left = 2-min-postcontrast, lower right = 7 min postcontrast). (B) In the corresponding subtraction images (upper left = subtraction 1-min-postcontrast minus precontrast, upper right = subtraction 2-min-postcontrast minus precontrast, lower left = subtraction 3-min-postcontrast minus precontrast, lower left = subtraction 7-min-postcontrast minus precontrast) the partially very strong signal increase after contrast injection is delineated. (C) In the "mosaic-image" (upper left = precontrast, upper right = 1-min-postcontrast, lower left = subtraction 1-min-postcontrast minus precontrast, lower left = T_2w-TSE image in identical sclice positions) some components of this multicompartmenatal lesion are brighter (arrow) than parenchyma in the T_2w-scan, some are dark. Note the typical behavior of myxoid fibroadenomas: Sharp borders and intact septations throughout the dynamic scans, partially very striking enhancement, often much stronger than the range of cancer-like enhancement, no "blooming-effect" and partial brightness in T_2w-images.

Fig. 4. (*Continued*)

lesion. After more than 20 years of clinical research a significant number of publications describe a very high sensitivity for MRM for detecting malignant lesions in the range of more than 95–100%. Even indications which had previously been described as "difficult", like the identification of Ductal carcinoma *in situ* (DCIS), are now accepted indications for MRM [99].

Technique

High temporal and spatial resolution is important for the detection and distinction between benign and malignant lesions. Today high-resolution dynamic techniques, i.e. the repeated imaging of the same slices before and in short time intervals after injection of contrast are used. The patient is placed in a prone position with the breasts hanging into a bilateral phased-array double breast coil after an iv-cannula had been placed in the cubital vein. The series of sequences in a dynamic MRM examination at 1.5 T includes (further technical details about the MRM examination are described elsewhere [101]:

1. a scout sequence (to clarify the position of the patient and breasts)
2. a coronal T_1-weighted Gradient-Echo-Sequence (T_1w-GRE-sequence) in a large field-of-view (FOV) including the axillary region and the neck region (to detect enlarged lymph nodes)
3. a transversal T_2w-TSE sequence.
4. a transversal T_1w-GRE sequence (i.e. the precontrast scan)
5. an iv injection of contrast (0.1 mmol/kg Gd-DTPA)
6. a sevenfold repetition of the precontrast scan (=nr. 4, in identical imaging parameters) every minute for the next 7 min
7. an automatic image subtraction
8. a coronal post-contrast scan (identical scan as nr. 2, so that any lesion in the breasts or the lymph nodes can be evaluated in two pre- and post-contrast orientations)
9. in the case of a breast implant, a silicone-selective sequence is added (focusing on the resonance frequency of silicone, which is 100 Hz lower than the resonance frequency of fat at 1.5 T.

The important T_1-weighted dynamic gradient-echo-sequences before and in short time intervals after the injection of contrast are performed as two dimensional-(2D) gradient-echo-sequences (TR/TE/flip-angle = 100 ms/4.7 ms/80°) in our institution. The FOV for scan nr. 4 is 350 mm, the slice thickness 3 mm for 36 slices in a matrix of 512 × 512 in a parallel imaging data aquisition. The aquisition time for sequence nr. 4 is 60 s.

Alternatively a dynamic three dimensional-(3D) gradient-echo-sequence can be performed which allows a better spatial resolution with thinner slices. However, the homogeneity of 3D-sequences in some machines is limited and artefacts caused by inhomogeneity deteriorate the kinetic data evaluation.

Another alternative is a dynamic fat-saturation-sequence (fat-sat-sequence) which usually also requires a following subtraction.

After the measurements, the kinetic data evaluation (signal-intensity-time-curves) in addition to the morphological analysis is made.

Modern MR-machines are able to acquire images in 512 × 512 matrices in time distances of each minute. Today parallel imaging techniques in fast gradient-echo-sequences (FLASH, FFE, GRASS) fulfill these prerequisites. Some teams prefer the so-called "fat-sat"-techniques by applying saturation pulses towards fat signal; these techniques suffered from signal inhomogeneities, longer measurement times and often single-breast examinations in the past and therefore could not be successfully applied in Europe [101].

Indications for MRM

The scientific results gained so far recommend MRM for the following indications:

1. The definite identification and/or exclusion of breast cancer in cases of unclear mammographic or sonographic breasts.
2. Clarification of number, size, and location of breast lesions, i.e. clarification of multifocality and/or multicentricity; thus enabling more precise planning for treatment.
3. Differentiation between scars and/or recurrent/residual tumors after previous operation/radiation.
4. Delineation of implants, implant-ruptures, and/or lesions around implants like inflammations or benign or malignant tumors.
5. Detection of primary tumors in the case of an unknown primary tumor following a positive lymph node.
6. Delineation of diseases in the contralateral breast before operation/radiation.
7. Detection of the early effect of chemotherapy after the first doses of anticancer drugs.
8. Examination of high-risk patients (family history, genetic risk like BRCA1 and BRCA2).

Discrepancies and Pitfalls

Despite striking results for the sensitivity the value of MRM is still in question because of variations in specificity, the high cost of the machine and examination, its inability to detect micro-calcifications, its role in detecting DCIS, questions about different dosages of contrast etc. As with other MR-examinations, patients with ferromagnetic particles, pacemakers, and operations that have taken place within the weeks prior to the examination, and patients undertaking hormone-replacement-therapy should not be included.

The major pitfalls consist of the following:

1. Signal-inhomogeneities in the image due to the rf-profile of the double-breast coil.
2. Signal-inhomogeneities and saturation artefacts in fat-sat images
3. Application of an inappropriate dose and type of contrast medium.
4. Measurement in an inappropriate ("opposed") echo-time where fat and water protons are oriented in different directions.
5. Inappropriate positioning of the breast using high compression of the breast and/or bent arms and lack of control of contrast uptake.
6. Incomplete injection of contrast medium and/or no detection of incomplete injection.
7. Movement of patient during the examination due to insufficient information.
8. Lack of kinetic analysis.
9. No inclusion of T_2-weighted-scans (T_2w-scans)
10. False data evaluation
11. Susceptibility artefacts due to small bleedings because of previous punctures and/or biopsies.
12. Omittance of normal enhancements and "inflow" effects.

Since the time intensity curve is (in addition to morphological evaluations) very important for the diagnosis, the signal intensity in the first post-contrast images, in particular, is absolutely crucial for diagnosis. This critical first contrast signal intensity image depends on exact measurement parameters. Injection time, injection site, sodium chloride bolus, length of plastic tube, arm position, tuning parameters are some of the major factors affecting this critical image signal intensity.

In our experience an increase of more than 90% in the first 90 s after the beginning of contrast injection ("90–90 rule") is a typical threshold for a malignant enhancement at 1.5T-2D-dynamic MRM. To reach this critical threshold measurement using a region of interest procedure (ROI) has to be performed carefully: Only the "vital" tumor areas show a critical initial enhancement followed by a plateau phenomenon or a washout effect. The inclusion of necrotic areas of the tumor or surrounding normal glandular or fatty tissue will deteriorate and falsify the effect of kinetic data evaluation. It is necessary to look for the fastest enhancing portion of the lesion.

It is also important not to include any enhancing focus and to describe it as malignant. Vessels are cut in different orientations in the slice and are therefore displayed in a round, oval or comet shaped manner. The detection of inflow phenomenon, the delineation of further vessels in other slices or other orientations or, if you have still any doubts, an additional MR angiography sequence clarifies the tiny enhancing area as a vessel or not.

Fat saturation techniques are in relatively widespread use in the United States. They allow a high spatial resolution, but have a limited value for kinetic data evaluation. Since a pre-pulse in a low bandwidth is necessary, the adjustment parameters in pre- and post-contrast scans are not identical. Current fat-sat techniques usually have a relatively high signal inhomogeneity, so that a quantitative evaluation is difficult and subtractions are difficult, though often necessary. The measurement time is in most cases longer than in non-fat saturation techniques and the "diagnostic window" for the detection of differences between benign and malignant enhancement criteria is restricted.

Fat suppression methods may be by temporal subtraction, which is ideal for fat suppression, since only enhancing structures are delineated as high signal intensity lesions. An alternative is fat suppression by pre-pulses with the above-mentioned limitations.

The injection of contrast medium is made in a bolus (3 ml/s) either manually or by an automatic injector followed by a post-contrast bolus of physiological sodium chloride of 20 ml (cubital vein) or 30 ml (lower arm/hand). The procedure should be explained to the patient before positioning in the machine. No movement of, or discussion with, the patient is recommended during injection. The dosage of contrast medium should not be higher than 0.1 mmol/kg. A higher dosage shortens the already short "diagnostic window", i.e. the time difference of only 1–2 min where the contrast uptake between malignant and benign lesions is sufficiently different in order to enable a differential diagnosis.

The evaluation begins by examining fatty tissue on both breasts to assess if the signal intensity of fat is constant. If this signal intensity of fatty tissue as an "internal standard" varies, consider changing receiver adjustment or field inhomogeneity effects or artefacts. In these cases a quantitative evaluation is difficult or impossible, since the technical problems overlap any morphological information.

Dynamic MRM should be performed in transversal scans, because in this orientation the identification of vessels, nipple, posterior borders of implants, fatty layer between parenchyma and muscle, signal homogeneity of the coil, and signal correlation with the aorta is possible. However, if the lateral border of the parenchyma towards the axillary region and/or lymph nodes is especially important, a dynamic MRM in coronal scans is advantageous. A sagittal orientation should be avoided because of doubled measurement time and the lack of correlation with the other breast, and the difficulty of detecting inflow phenomenon and hormone effects. This image orientation might be acceptable if sagittal images can be acquired simultaneously from both breasts.

If only the axillary region is important, the rotation of the phase encoding direction towards a dorso-ventral orientation is recommended to keep the lateral axillary region free of phase encoding artefacts.

It is of crucial importance to use echo times where fat and water protons are in “in-phase” conditions, because Gd has a signal-*increasing* effect on the water protons in the voxel only in these echo times. Particularly tiny reticular structures like DCIS or lobular cancers can be imaged only in these “in-phase” images. “In-phase” conditions for 1.5 T are even numbers of 2.4 ms, i. e. 4.8, 9.6 ms etc. Odd numbers of 2.4 ms, for example 7.2 ms are “forbidden” because of the “opposed effect” of water and fat protons. This effect is field-strength dependent and should be adjusted according to the field strength which is used.

During the dynamic examination it is essential not to change tuning parameters between scans and to guarantee identical pulses in pre- and post-contrast scans. No change of pulses should be allowed between pre- and postcontrast scans. Only under these conditions is a correct signal intensity/time evaluation possible.

The pre-contrast signal intensity of parenchyma should be in a typical range for this sequence. If it is too low, this may be caused by an inappropriate receiver adjustment or inappropriate coil design; try to repeat the receiver adjustment. If this pre-contrast signal intensity is too high, it could also be an inappropriate receiver adjustment or a medical/biological reason (bleeding after puncture/biopsy, hormone effect, pregnancy, previous operation, and/or radiation).

Diagnosis of breast lesions in MRM is always made by a combined morphological and kinetic analysis. It is the main feature of MRM that tumor typical “tumor-angiogenesis” can be detected by signal-intensity-time-curves. A typical malignant lesion shows the striking initial increase (wash-in phenomenon) within the first 1–2 min followed by either a constant signal (plateau phenomenon) or—more specifically—a decrease in signal intensity (washout effect). The sudden increase and the following constancy or washout effect make the “cancer-corner” of the signal-time-curve. Benign lesions normally show a slower initial increase which is continuously rising over the complete dynamic examination. The distribution of a lesion is described as regional or patchy or diffuse or symmetric; the lesion itself is morphologically described as a focal mass with sharp or non-sharp margins, linear, linear-branched or segmental aspects. The initial and late enhancement is described as being homogeneous, heterogeneous, rim enhancement, bright or dark septations after contrast and centripetal or centrifugal filling effect over time. A centrifugal filling (from inside to outside) is directed mainly towards a benign lesion, a centripetal filling (from outside to inside) towards a malignant lesion.

Another major mistake is the inclusion of patients under hormone-replacement-therapy for MRM, because hormone effects cause bilateral, patchy, continuously enhancing spots which are confluent on late scans [103] and thus might be difficult to separate from bilateral DCIS or lobular cancers. However, in most patients DCIS and lobular cancers show unilateral enhancements and, in two-thirds, also a cancer-like wash-in and washout effect.

Future Challenges

At present MRM is classified as an additional diagnostic tool in all cases of unclear mammographic and sonographic situations. The medical community needs teaching, training, increased experience, and consensus. MRM will allow a precise detection of cancers in a size as small as 3 mm. For this purpose special techniques providing high spatial and temporal resolution are needed.

New specific contrast agents might enable a selective display of specific cancers and differentiate them from other lesions in the breast and in the whole body as well.

The combination of MRI and MR-spectroscopy will probably increase the overall accuracy of MRM.

Today modern “high-field MR-devices” (high-field for imaging means above 1.0 T) do not allow direct access to the breast during data acquisition. The patient has to be in the isocenter of the magnet field during imaging and must be moved outside the machine for a following intervention. The position of a wire marker, a core biopsy or a laser fibre has to be checked by a following MR-image, thus increasing measurement time, artefacts, and pitfalls. A MR-compatible robotic system for simultaneous imaging and immediate biopsy/intervention at high field strength is in clinical testing.

Combining MRI and therapy in one session—at least for lesions smaller than 2 cm—might enable a “one-stop-shop” procedure of detection and simultaneous removal in one single examination [104–105]. Preliminary tests applying laser therapy, radio frequency therapy, or cryotherapy have been promising so far [106–107] as has receptor-specific near-infrared-imaging *in vitro* [108].
